Keywords

Asymmetric Division
Cellular division of stem cells wherein one daughter cell remains a stem cell and retains stem cell properties, while the other daughter cell begins the process of determination.

Blastocyst
A stage in the development of the embryo when the daughter cells derived from the fertilized egg (blastomeres) form a cyst. The outer layers of the cyst form the fetal membranes; the inner cell mass develops into the fetus.

Determination
The process by which cells lose potential and gain specialized function. This is also known as *differentiation*.

Embryonic Stem Cells
Cells from the first six to seven divisions of the fertilized egg found in the inner cell mass of the embryo. Embryonic stem cells are isolated from blastocysts before implantation into the uterus.

Potential
The property of a stem cell that allows it to give rise to progeny that are able to differentiate into various cell types. A totipotent cell can give rise to progeny that differentiate into all of the various mature cell types of the organism. A multipotent or pluripotent cell can differentiate into many of the cell types of the organism, but not into all cell types.

Stem Cell
A cell that renews itself after division so that it is never lost by differentiation.

Symmetric Division
Cellular division of stem cells in which each daughter cell remains a stem cell and retains the properties and potential of the mother cell.

A stem cell is a self-renewing cell that is both the first cell of a new organism and the cell that is responsible for the renewal of adult tissues. The fertilized egg is the ultimate stem cell. Following conception, the fertilized egg divides to produce identical daughter cells, which later give rise to progeny that provide all of the cells of the developing organism. These are called *embryonic stem cells* (ESCs). In the adult organism, individual stem cells are responsible for not only normal tissue renewal (*adult stem cells*) but also for sexual reproduction (*germ stem cells*). The adult stem cell divides to give rise to two daughter cells, one of which remains a stem cell; the other begins the process of differentiation. Stem cells in the adult not only replace the mature dying cells of specific tissues but may also have the potential to contribute to broader repair of injured tissues. Stem cells of the adult are also the cells that give rise to cancers. It is anticipated that treatment of genetic diseases and repair of damaged organs will be accomplished by exploitation of the properties of either embryonic or adult stem cells.

1
Properties of Stem Cells

1.1
The Fertilized Egg and Embryonic Development

The fertilized egg is a single stem cell, which divides to give rise to progeny that can differentiate into any of the specialized cells of adult tissues, as well as the membranes and placenta of the fetus (Fig. 1). During early embryonic development, the daughter cells of the fertilized egg, called *blastomeres*, clump together to form a cluster of cells known as a *morula*. At each division, the blastomeres are reduced in

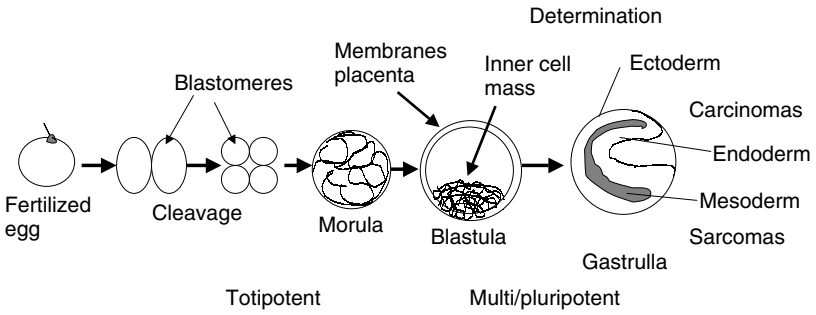

Fig. 1 Early development of the embryo. Division of the fertilized egg results in the formation of daughter cells called *blastomeres*, which form a ball of cells called a *morula*. After six or so divisions, a cavity appears at one end of the morula to form the blastocyst. Until this stage, each of the cells divides evenly to produce two daughter cells, each of which retains the same characteristics, that is, they are totipotent. The inner cell mass of the blastula is the source of ESCs (see below). Invagination of one pole of the blastula leads to formation of the primitive germ cell layers, with formation of the gastrula. During gastrulation and later formation of the fetus, the daughter cells lose potential as they gain specialized function. This process is known as *determination* (see below).

size, but each embryonic blastomere is able to produce all differentiated cell types, that is, it is totipotent. Eventually, as the number of blastomeres approaches 64 cells (six divisions), a cell-free center appears in the expanding cluster of blastomeres, and a hollow sphere of cells is formed, containing a clump of cells at one pole, the inner cell mass. This is the blastula. In humans, this process takes five to six days, as the morula moves down the fallopian tube of the uterus to the uterine cavity. The blastula then implants in the lining of the uterus (endometrium), where the outer layers of the blastula form the fetal membranes and placenta, and the inner cell mass begins the process of determination or differentiation (see below), to produce branches (lines) of cells that form the differentiated organs of the adult. At this stage, the outer cells of the blastocyst are believed to be no longer totipotent as they become committed to the fetal membranes and placenta. However, the inner cell mass remains multipotent until it becomes committed to the cells that make up the germ layers of the developing fetus. As the inner cell mass develops, the daughter cells begin to acquire properties different from one another, so that specific regions are formed that are destined to become different components of the developing embryo, a process known as *gastrulation*. During gastrulation, the blastula is rearranged to form layered ''germ'' zones known as *ectoderm* (outer skin), *mesoderm* (middle skin), and *endoderm* (inner skin), which are destined to form the adult organs. Skin, dermal appendages (including breast), and neural tissue are derived from ectoderm; connective tissue, muscle, bone, and blood vessels from mesoderm; and the gastrointestinal (gi) tract and glandular organs from endoderm. The relationship of cancer to the development of the gastrula is exemplified by the fact that cancers that arise from endoderm- and ectoderm-derived cells are

called *carcinomas*, whereas cancer that arise from mesoderm-derived cells are called *sarcomas*. For practical purposes, embryonic stem cells (ESCs) are the cells of the inner cell mass that are obtained from the blastocyst prior to implantation.

1.2 Symmetric and Asymmetric Division

ESCs divide to produce daughter cells with the same properties (symmetric division), whereas adult stem cells divide to produce daughter cells with different properties (asymmetric division, Fig. 2). During early embryonic development, symmetric division leads to a rapid exponential increase in the number of ESCs. After the first six or eight divisions, there is a gradual switch from symmetric division to asymmetric division, as differentiated organs are formed. Organogenesis involves both a change in the character of the cells and a loss of cells (programmed cell death, or apoptosis). Finally, in the adult during normal tissue renewal, the number of newly generated cells equals the number of terminally differentiating cells, so that the cell number in the organ remains at a constant level. This is accomplished by asymmetric division, in which one daughter cell retains the properties of the stem cell while the other daughter cell begins the process of determination (differentiation). However, the adult organs can respond to stress or injury by a shift to symmetric division when an increased number of cells is beneficial, such as an increase in the number of blood cells in response to reduced availability of oxygen at high altitudes, or the replacement of lost liver cells after toxic or viral liver injury. How asynchronous division is controlled is not well understood. In germ cells, one pole of a dividing cell contains protein complexes that are different from those present at the other pole of the cell, or one of the poles is anchored to a supporting cell or membrane, whereas the other pole is not, so that one daughter cell remains attached to a surrounding ''niche'' cell and remains a stem cell, whereas the other does not and begins the process of determination.

1.3 Stem Cells and the Origin of Life

In the fourth century B.C., Aristotle studied the early stages of human development in the uterus and concluded that the embryo was derived from the mother's menstrual blood. This conclusion was consistent with the hypothesis of spontaneous generation that living animals arise *de novo* from slime or decaying matter. This and similar concepts of the origin of life were generally accepted for over 2000 years until the hypothesis that life did not arise spontaneously, but only from preexisting life (*omne vivum ex vivo*), was pronounced by Leydig in 1855. Rudolph Virchow, the father of pathology, extended this to postulate that all cells in an organism are derived from preexisting cells (*onmis cellula e cellula*). Thus, all the cells of the human body arise from a preexisting stem cell, the fertilized egg. In 1864, Louis Pasteur formally disproved the spontaneous generation hypothesis through carefully controlled experiments in which he demonstrated the failure of microorganisms to grow (corruption) in sterilized broth-containing vessels with long necks that prevented ambient organisms from entering.

The dominant hypothesis of the 19th century was that a preformed individual

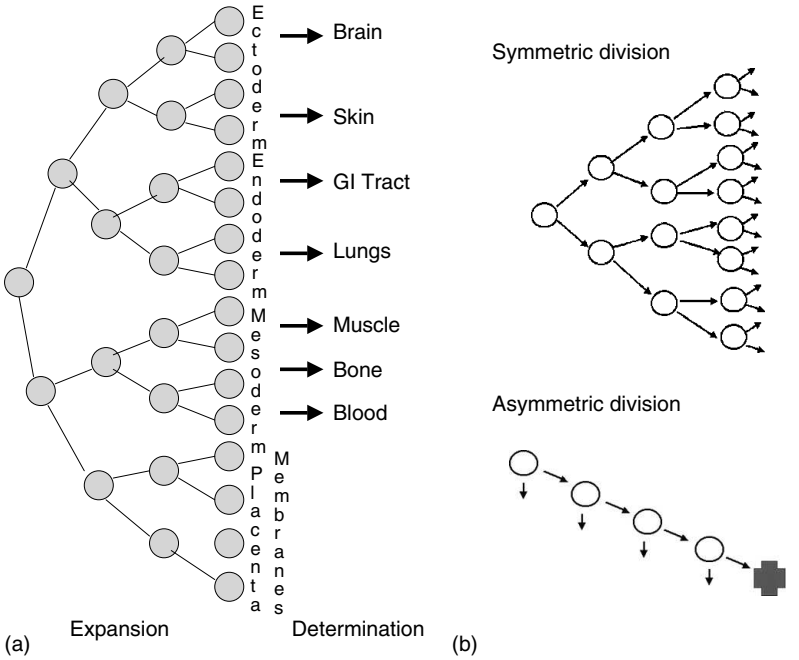

Fig. 2 Properties of stem cells. (a) Stem cells and organogenesis. During embryonic development, the ultimate stem cell, the fertilized egg, gives rise to progeny that remain totipotential as the population expands. Then, determination occurs and the cells begin to lose potential and begin to gain the specialized functions required for the formation of mature organs. As the adult organs form, the stem cells alter the nature of the division, so that one daughter cell begins the process of determination, while the other daughter cell remains a tissue stem cell (asymmetric division). The first determination step results in differentiation of cells that form the membranes and placenta of the developing embryo. Then, the cells remaining in the inner cell mass form the primitive germ layers called *ectoderm*, *endoderm*, and *mesoderm*. The cells in these germ layers then differentiate further into adult organs. (b) Symmetric and asymmetric division. During symmetric division, each cell divides and gives rise to two daughter cells with the same potential. This is a property of ESCs. During asymmetric division, a property of normal tissue renewal in the adult, each progenitor cell gives rise to one daughter cell that remains a progenitor cell plus one daughter cell that begins the process of determination to a terminally differentiated cell (i.e. asymmetric division). The number of cells increases exponentially during early embryogenesis, but the cell number remains constant during normal tissue renewal, as the number of new progenitor cells equals the number of cells destined to die.

resided in the egg or the sperm. This preformed individual was called a homunculus. The homunculus in the egg was activated to develop after stimulation with sperm, or the homunculus in the sperm was activated to develop when provided an appropriate environment in the uterus. By the early 1900s, it had been definitively shown that this concept was incorrect, and that the embryo formed by

the fertilization of an egg that developed in the ovary of the female by fusion with a sperm provided by the male. The product of the union of a sperm with an egg is the primordial totipotent stem cell.

1.4 The Cycle of Life and Various Kinds of Stem Cells

According to the principles derived from Leydig, Virchow, and Pasteur, life, as we know it, neither ends nor begins, but is continuous. The adult human, for example, is only one stage in the cycle of life (Fig. 3). The life of an individual begins with fertilization of the egg through formation of a fetus. Totipotent cells in the developing fetus migrate to the genital ridge. In adults, they produce germ stem cells in the gonads. Germ cells give rise to gametes (egg and sperm) by reduction division (meiosis), resulting in half the genetic information of the adult cells. Genetic reconstitution occurs when the sperm fertilizes the egg. In this process, life is continuous; it is neither created nor destroyed. As the cycle of life is manifested, successive types of stem cells are produced: embryonal, fetal, germ, and adult. The properties and promise of each of these types of stem cells will be presented below.

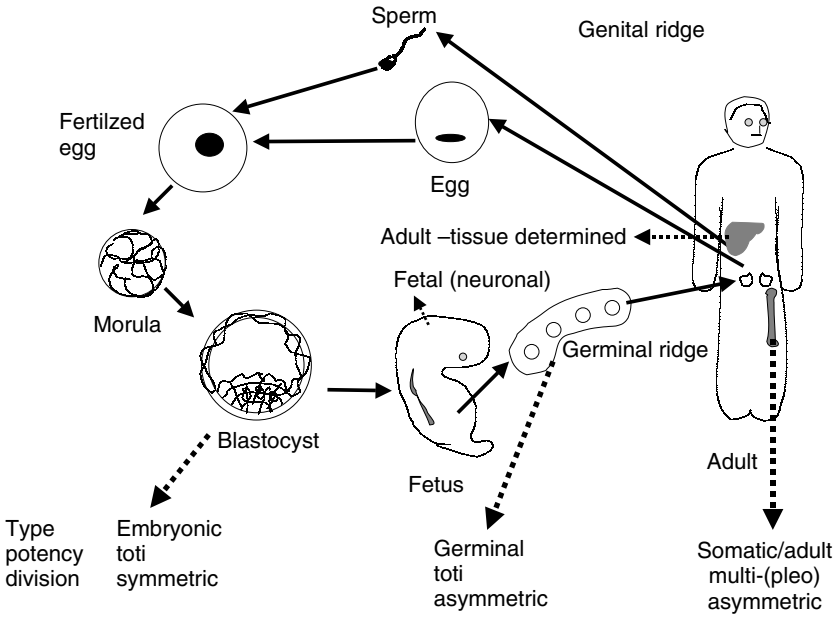

Fig. 3 Stem cells and the cycle of life. Stem cells of various kinds form a cycle of life. The fertilized egg divides to produce ESCs. When the fetus is formed, a set of germ cells develops in the genital ridge that gives rise to the germ cells in the gonads in the adult. These, in turn, produce egg or sperm that unites to form the fertilized egg, thus completing the cycle of life. In addition, there are in the adult various types of stem cells with differing potentials. The various types of stem cells, embryonic, germ, fetal, and adult (somatic), are each the subject of intense investigation for determination of their potential to restore or replace damaged cells (stem cell therapy).

2
Determination and Potential of Stem Cells

2.1
Determination/Differentiation

The process of the loss of potential and the gain of specialized function is known as determination or differentiation. In this process, the *totipotent stem cells* of the blastomere give rise to *multi/pluripotent cells* of the germ layers. These, in turn, give rise to tissue-determined stem cells of the developing organs. A change from symmetric to asymmetric division is a consequence of determination or differentiation. Tissue determination is accomplished in progenitor cells through interaction with other cell types. For example, determination of primitive gut cells into cells of the liver or pancreas takes place in association with developing endothelium and mesenchyme. As the cells become specialized into tissue, their potential is increasingly limited, and they finally differentiate to terminally differentiated cells. The molecular signals controlling determination are not well understood. Cellular signaling pathways, such as Oct-4, Wnt/β-catenin, Notch, BMP (bone morphogenic protein), Janus family kinase, and sonic hedgehog signaling pathways are under intense study for elucidation of their possible roles in determining which cells differentiate and which remain stem cells.

2.2
Terminology of Potential

The terminology used regarding cellular potential is listed in Table 1. The term totipotent should be reserved for those stem cells that can give rise to all of the differentiated tissues of the body as well as the fetal membranes and placenta, that is, the ESCs prior to blastulation. The terms multipotential and pluripotential are often used for the same attribute, the ability of a given stem cell to form many or all of the cells of the body, but not the cells of the fetal membranes, that is, the cells of the inner cell mass. In an official NIH primer released in 2000, pluripotent was defined as ''capable of giving rise to most tissues of an organism,'' and totipotent as ''having unlimited capacity'' (www.nih.gov/news/stemcell/primer.htm). The potential decreases with progression of development of the embryo. However, as will be described in more detail below, some adult tissue stem cells appear to retain the potential to differentiate into cells of other lineages. Thus, these adult cells express unexpected or excess potential and are termed *pleopotent stem cells* (Table 1, and see below).

Tab. 1 Terminology of potential (plasticity).

Prefix	*Meaning*	*Example*
Toti	All	Embryonal
Multi	Many	Hematopoietic
Pluri	Some	Hematopoietic
Pleo[a]	More, excess	Hematopoietic
Oligo	Few	GI stem cell
Tri	Three	Bronchial lining
Bi	Two	Bile duct
Uni	One	Prostate

Source: The Random House Dictionary of the English Language.
[a] Recent evidence indicates that some cells in the tissues used as examples of determined potential may actually have more potential than was previously appreciated. For example, the skin or bone marrow may contain stem cells with the potential to form tissues of other organs. The term pleopotential is suggested for this property.

2.3 Dedifferentiation

Dedifferentiation, the reversion to a less-differentiated state of a cell after commitment to a more mature functional state, is difficult, if not impossible, to demonstrate in mammals, but it occurs during regeneration of tissues in fish and amphibians, such as Zebrafish, salamanders, and *Xenopus laevis* larvae. During limb regeneration in salamanders, the amputation site is covered by a thin layer of epidermis. Then, the major regeneration of the tissues of the lost limb is accomplished by a group of about 10 000 cells arising by dedifferentiation from the remaining muscle, cartilage, dermis, and glial (Schwann) cells, which form a cluster of undifferentiated cells called a *blastema*. These dedifferentiated cells then redifferentiate to form the mature cartilage, muscle, nerve, and so on, of the regenerated limb. This process appears to be limited to cells of mesenchymal origin as the overlying epidermis is restored by the epidermal layer and not the blastema. Thus, the differentiated muscle, nerve, and connective tissue cells of the salamander limb appear to retain the multipotency of more primitive mesodermal cells, even after differentiation into cells with mature function. It is not known why mammalian limb cells appear not to retain this capacity. One hypothesis for the cellular origin of cancer is that mature cells dedifferentiate to less-mature stages of cellular development, at which growth cannot be controlled. However, as will be discussed in more detail below, this appears less likely than the alternative hypothesis, namely, that cancer represents cells arrested in a stage of maturation at which they continue to proliferate without differentiating into mature nondividing cells (terminal differentiation).

3 Embryonic Stem Cells

3.1 Isolation and Culture of Embryonic Stem Cells

Under optimal conditions, cells from the inner cell mass of the preimplantation embryo (ESCs) are able to proliferate indefinitely and, under inducing conditions, to undergo determination and then to differentiate into the cells of any of the tissue types of the adult. In contrast, after formation of germ layers, most somatic progenitor cells have limited life spans and they exhibit decreasing differentiation potential as mature organs are formed. In practice, ESCs are obtained from preimplantation blastocysts created for purposes of *in vitro* fertilization (Fig. 4). Human oocytes fertilized *in vitro* will grow to the blastocyst stage in culture. Subsequent transfer of the *in vitro* fertilized embryos to the uteri of infertile patients, supplemented with luteal support, eventually led to the successful clinical application of *in vitro* fertilization. During *in vitro* fertilization, several hundred human oocytes are fertilized, and many blastocysts are produced. These are usually frozen, so that they can be used if the first uterine transplantation of four to six blastocysts is not successful. At present, there are hundreds of thousands of frozen human blastocysts available for culture. To obtain ESCs, the outer layer of the cells of the blastocyst is removed, destroying the embryo, and the inner cell mass cells are dispersed and placed into tissue culture. It is a common misconception that ESCs

are obtained from aborted fetuses. This is simply not correct. At the time of induced abortion, the embryo or fetus is far past the blastocyst stage of development where ECSs could be obtained.

Through adjustment of the conditions of culture, addition of different growth factors, or transfection of the cells with genes for transcription factors, the ESCs can be directed to differentiate into various cell types. For example, high glucose in the medium or transcription with pancreatic transcription factors can induce the cells to differentiate into pancreatic cells; addition of fibroblast growth factor (FGF) will induce the cells to become neuronal cells; addition of epidermal growth factor (EGF) will induce formation of glial cells. Through manipulation of the culture conditions, ESCs can be induced to differentiate into blood islands, muscle, connective tissue, neurons, macrophages, liver, and other cell types. ESCs injected into a normal blastocyst will incorporate into the developing embryo to form a chimeric individual; the organs of the

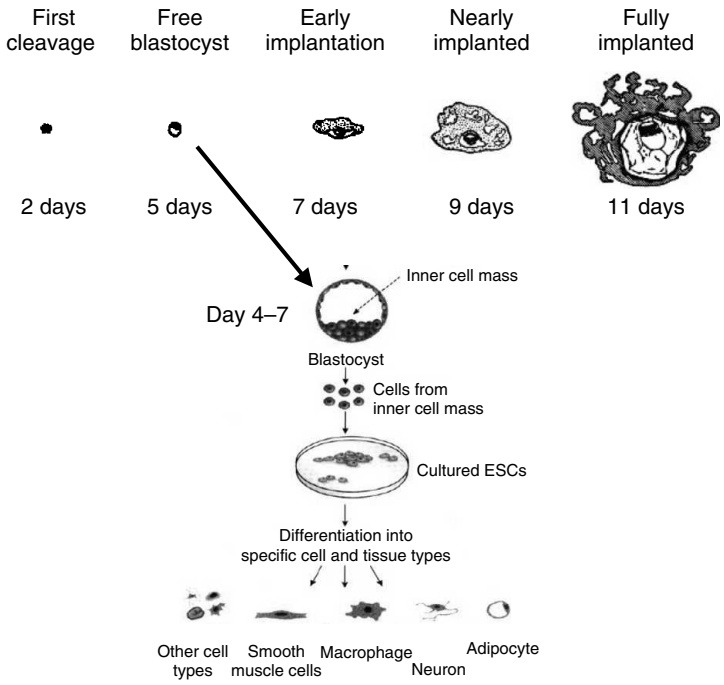

Fig. 4 Isolation and culture of human embryonic stem cells. ESCs are isolated from the preimplantation blastocyst cultured after *in vitro* fertilization. The inner cell mass cells from the blastocyst are cultured in special medium, and single cells are selected to produce cell lines. The cell lines are then cultured with selective growth factors, or transfected with tissue-specific promoters, to induce differentiation to more mature cell types. Modified from: Arey, L.B. (1974) *Developmental Anatomy*, W.B. Saunders Co., Philadelphia, PA and National Research Council – Institute of Medicine (2002) *Stem Cells and the Future of Regenerative Medicine*, Washington, DC, http://stemcells.nih.gov.

individual that develops will contain a mixture of cells derived from the ESCs and the blastocyst. The tremendous potential for the therapeutic use of ESCs is now only limited by our knowledge of how to induce these cells to differentiate into the cell type that we want, when we want them to, and how to manipulate them so that they will incorporate into adult tissues after transplantation.

3.2 Embryonic Stem Cell Therapy

The potential of the *in vivo* use of ESCs for therapy was demonstrated when it was shown that injection of ESCs into lethally irradiated mice could restore the lost bone marrow stem cells. Difficulties in using ESCs for replacement of adult tissues are the low efficiency and long time required by ESC for the process of differentiation into functional adult cells. This may be addressed either by using adult stem cells (see below) or by directing ESCs to a specialized tissue pathway *in vitro* prior to transplantation. ESCs may require a series of signals in order to produce progeny of a more differentiated type. For example, specialized culture conditions, including exposure to and withdrawal from FGF or culture with FGF and other growth factors, allow generation of neural stem cells, which will incorporate into developing mouse brain, and will migrate into damaged zones in the mouse brain and reconstitute the damaged tissues.

Since the ESCs will express histocompatibility markers when they differentiate, ESC therapy is only possible when the donor of the ESCs and the recipient are histocompatible. In preclinical models, cells are transplanted between inbred mouse strains or human cells are transplanted into immunodeficient mice, which will not reject the human cells. In order to carry out successful ESC therapy between histoincompatible individuals, it is necessary to obtain ESCs that bear the same histocompatibility genes as the recipient. The method proposed to meet this requirement is nuclear transplantation.

4 Nuclear Transplantation and Reproductive Cloning

ESCs with genetic characteristics of an adult individual may be obtained by transplantation of an adult nucleus into an enucleated oocyte from a different individual (Fig. 5). The microenvironment of the egg allows expression of the genes of the transplanted adult nucleus and results in development of a ''cloned'' embryo, which carries the genotype of the nuclear donor. The egg with the transplanted nucleus is cultured *in vitro* to the blastocyst stage. At this point, the cells of the developing blastocyst may be cultured as ESC lines, which can then be transplanted back into the adult nuclear donor without immune rejection. If the donor is lacking a critical gene, it can be transfected into the ESCs and then transplanted into the adult, thus effecting nuclear transplantation. The blastocysts may also be transplanted into the prepared uterus of a surrogate foster mother, in whom they may develop into a mature individual that is a clone of the nuclear donor (reproductive cloning). In experimental animals, this procedure has a very low success rate (generally less than 1%). Although reproductive cloning has been accomplished in several mammalian species, including primates, there are inherent problems in the procedure as the cloned individual exhibits accelerated

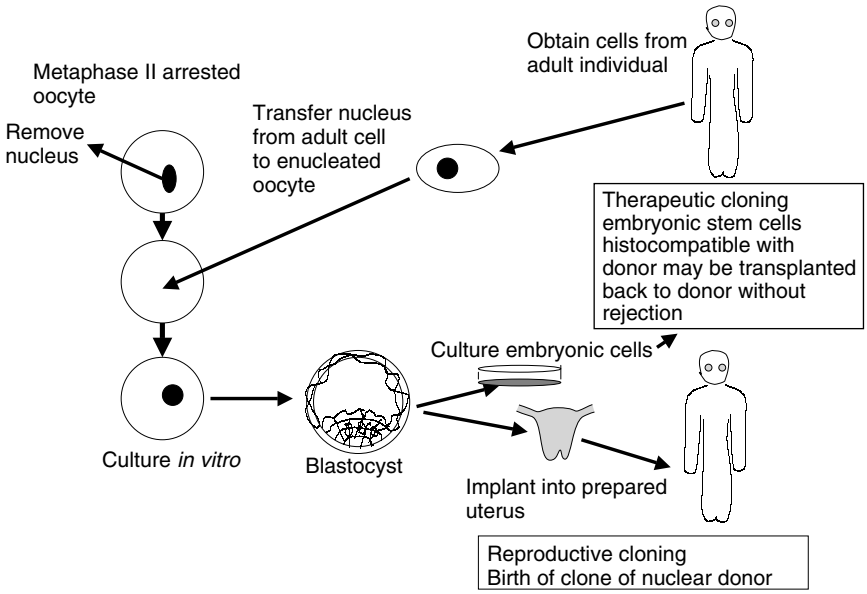

Fig. 5 Nuclear transplantation and cloning. Nuclear transplantation and cloning are accomplished by transferring the nucleus of an adult cell to a fertilized egg from which the nucleus has been removed. The developing egg is able to reactivate expression of the genes of the donated nucleus and to proliferate so as to form a blastocyst, which will have the same nuclear genes as the adult donor. The ESCs of this blastocyst can now be injected back into the donor of the nuclei and the ESCs will not be rejected, because they will express the same major histocompatibility antigens (MHCs) as the recipient. These ESCs could be used to replace a damaged organ, or they could be transfected with a replacement gene that is malfunctioning in the recipient (therapeutic cloning). The blastocyst may also be transplanted into a prepared uterus to develop into a clone of the nuclear donor (reproductive cloning is given in Table 2).

aging. Nuclear transplantation is generally viewed as ethically acceptable, since the blastocyst has been created for the purposes of *in vitro* fertilization and is destroyed before implantation. Thus, a truly viable embryo is not produced. However, reproductive cloning is not considered acceptable for application to humans.

The critical role of the interaction of the cytoplasmic environment of the oocyte and the transplanted nucleus of the donor cell is exemplified by experiments in which the nucleus of a mature cell is transplanted into the cytoplasm of a less-mature cell. In classic embryology, determination was understood as a one-way process: once a cell is fully differentiated in the adult, it is stable and not able to dedifferentiate. Thus, it was thought that the only nuclei from adult cells that could be programmed to produce a new organism would be those of a tissue stem cell. In experiments using nuclei from tadpoles, the potential of the nucleus was progressively lost during gastrulation. In the case of the cloning of sheep, for example, Dolly, nuclei from a day-nine embryo, a 26-day fetus, and the mammary gland of a six-year old ewe in the last trimester of pregnancy

were used; the use of the latter donor implies that nuclei from adult mammals retain all of the potential of the germ cells. However, the exact nature of the cells in the mixture used for cloning that contribute the nuclei, in the case of the transplant from mammary gland of the pregnant ewe, was not identified. The mammary epithelium during the third trimester is actively proliferating, and the proliferating gland contains large numbers of active progenitor cells. Since the number of nuclei in the mature adult tissue that can do this appears to be vanishing small, it is likely that those nuclei from an adult tissue that are capable of ''reprogramming'' in an oocyte may actually be the tissue progenitor cells or even the putative circulating totipotent stem cells of the adult.

On the other hand, under some circumstances, the differentiated state appears to be reversible. Transfer of nuclei from differentiated adult cells into an oocyte can result in the restoration of the totipotency of the nucleus in the oocyte. This appears to be true even for mature T and B cells, which have a rearranged T-cell receptor and immunoglobulin genes respectively. Every tissue in mice cloned from a B cell had the same immunoglobulin gene rearrangement as the original donor nucleus.

5
Germ Stem Cells

Germ stem cells are those cells in the reproductive organs that give rise to sperm or eggs. In practice, germ cells from the adult are not usually used for therapy; germ cells from the genital ridge of fetal animals are more readily obtained. Even so, it is more difficult to obtain and culture these cells than ESCs, and much less work has been done on them.

5.1
Germ Cell Niches

Early in embryogenesis, a few cells are designated to become germ cells; the cells that differentiate into egg or sperm in the adult individual. These cells migrate into the primitive gonad (genital ridge) and differentiate into female or male germ cell precursors, depending on the presence of two X chromosomes (female) or one X and one Y chromosome (male). In *Drosophila*, germ cells, both in the female's ovary and in the male's testes, reside in specialized tissue (niches) that control the division of the stem cells; thus, after mitosis, one daughter cell remains a stem cell and the other becomes a transit-amplifying cell that enters the process of producing sperm or egg cells (asymmetric division). During this process, the germ cells undergo reduction division or meiosis, whereby the number of chromosomes in each cell is reduced by half, so that each gamete contains a single set of chromosomes. Other cells in the organism contain two sets of chromosomes. When the egg is fertilized by sperm, the nuclei of the egg and sperm combine to reform a complete set of two chromosomes. In the testes, the germ cells surround a central core of supporting somatic cells known as the *hub*; in the ovary, the germ cells are wrapped inside somatic cells in a structure known as an *ovariole*. Upon division, the daughter cell next to the hub or at the end of the ovariole remains a stem cell, whereas the other distal daughter cell begins the process of determination to sperm or egg. Germ stem cell niches are critical for normal maturation and asymmetric division of germ cells. When germ cells are

displaced from their niches, teratocarcinomas may develop, indicating a role for the tissue microenvironment in controlling cell proliferation and differentiation.

5.2 Teratocarcinoma

Germ stem cells will express uncontrolled proliferation, haphazard differentiation, and tumor formation when growth controls normally placed on the developing germ cells are missing. For example, transplantation of germ cells from adult testes of mice into the genital ridges of 21-day-old fetal mice results in uncontrolled differentiation and tumor formation (teratocarcinoma). Teratocarcinomas are cancers of mixed cell types and may contain essentially all cellular elements of adult tissues, including brain, bone, teeth, bone marrow, eyes, endocrine glands, muscle, skin, and intestine, arising from all three germ layers as well as placenta and yolk-sac tissue.

The environment of the normal blastocyst can control the malignant potential of teratocarcinoma tumor cells. After transplantation into the inner cell mass of normal developing murine blastocysts, malignant teratocarcinoma cells will incorporate into the developing embryo with production of mosaic or chimeric mice, which contain normally functioning tissues derived from the tumor cells. These studies not only demonstrate the totipotential of germ cells and the teratocarcinomas derived from them but also the principle that the differentiation potential of totipotent cells – and in fact their ability to produce cancers – is controlled by appropriate environmental signals. These findings raise the possibility that other types of stem cells, including ESCs, will also undergo loss of growth control and will produce cancer if placed in the ''wrong'' environment.

6 Adult (Somatic) Stem Cells

The cells in normal adult organs are continuously replaced through a series of asymmetric cell divisions of adult stem cells. The rate of renewal varies in different organs. For example, skin, gastrointestinal epithelial cells, and some blood cells (polymorphonuclear cells) will be completely replaced in two weeks or less, whereas replacement of other tissues such as liver (approximately two years) or brain (a lifetime) are much more slowly replaced, if at all.

6.1 Normal Tissue Renewal

Normal replacement of adult tissue cells is accomplished by proliferation of tissue-determined stem cells, which differentiate into more mature cells that can no longer proliferate, and eventually die (Fig. 6). In the process of normal tissue renewal, in contrast to the symmetric division that occurs during embryologic development, division is asymmetric, with one daughter remaining a stem cell and the other beginning the process of determination. Normal renewal is accomplished by cohorts of transit-amplifying cells or progenitor cells, which are the daughter cells of the more primitive stem cell. The most primitive tissue stem cell normally does not divide, but it can be stimulated to proliferate if there is an increased demand for more cells (see hematopoietic progenitor cells, Sect. 6.3 below). When a tissue progenitor cell divides, one daughter cell remains a progenitor cell, whereas the other begins the process of determination, eventually producing a terminally differentiated cell, which in time dies. To maintain the total number of cells in an adult organ in equilibrium, the number of progenitor cells

that divide must equal the number of cells that differentiate and die. A comparison of the rates of normal tissue turnover in various organs is given in Table 2.

6.2 Plasticity of Adult Stem Cells

In classic embryology, determination is considered a one-way process. For example, once primitive endoderm becomes committed to forming liver, it is not able to dedifferentiate or ''transdifferentiate'' into another tissue type. However, there is increasing evidence for an unexpected plasticity of tissue stem cells. Adult stem cells of a given tissue, for example, blood, are able to differentiate into cells of other tissues, including liver, brain, and skin, of other germ layers. This is unexpected plasticity (*pleoplasticity*). Of particular importance is the presence of pleoplastic stem cells in the bone marrow that could be used for replacement of damaged cells in other organs of the same individual (autologous). Thus, it might be possible to clone cells from the bone marrow that could be exposed to selective determination signals *in vitro* and then be transplanted back into the same individual to replace lost cells in a specific organ. However, it has not been possible to obtain clones of bone marrow–derived stem cells with this potential. On the other hand, intravenous injection of

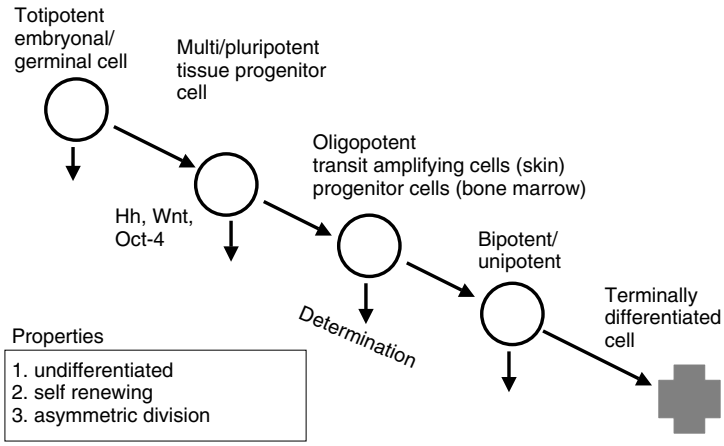

Fig. 6 Stem cell model of tissue renewal. Stem cells are part of a continuum of cell lineages with decreasing potential and increasing differentiated function. Depicted is a postulated lineage of cells including ESCs, tissue stem cells, transit-amplifying cells (progenitor cells), and terminally differentiated cells. ESCs give rise to tissue-determined stem cells during fetal development. In adults, the tissue-determined stem cell is usually quiescent and does not proliferate unless there is an increased need to produce new tissue cells. Normal tissue renewal is accomplished by transit-amplifying cells, which are the daughter cells of the tissue stem cells. In rapidly renewing tissues such as the bone marrow or gi tract, the population of transit-amplifying cells is relative large, whereas in slowly renewing organs, such as the liver, the number of these cells is very low. In normal tissue renewal, the number of new tissue cells produced essentially equals the number of cells that are lost by apoptosis or sloughing, so that the total number of cells in the tissue remains the same.

Tab. 2 Turnover and potential of progenitor cells in some adult organs.

Organ	*Replacement time*	*Potential*
Bone marrow	2–3 days (polys)	Multi/pluripotential (?pleo)
GI lining	2–4 days	Quadripotential (4 types)
Skin	2 weeks	Bipotential
Liver	1–2 years	Bipotential
Brain (neurons)	Lifetime	Unipotential[a]

[a] Mature neurons cannot divide, but neuronal progenitor cells are present in some parts of the adult brain. A generalization that can be made from these data is that the faster the cell turnover in a given organ, the more likely it is that that organ contains a stem or progenitor cell with the potential to form other cell types.

large numbers of autologous bone marrow cells allows the organ to select a few cells among the millions of transplanted bone marrow hematopoietic cells that might be able to differentiate into the cells of that organ's tissue.

6.3 Hematopoietic Stem Cells

6.3.1 Hematopoietic Cell Lineage

One of the most rapidly replaced tissues in the body is the blood. The hematopoietic or blood-forming cells are located in the bone marrow. The existence of an undifferentiated stem cell for blood cells ("gemeinsame Stammzelle") was hypothesized as early as 1917. This hematopoietic stem cell's lineage extends from the resting stem cells to transit-amplifying precursor cells to mature circulating blood cells (Fig. 7). The resting stem cell normally does not proliferate; production of new blood cells is accomplished by proliferation of the precursor or transit amplifying cells. The ability of the bone marrow stem cells to form colonies of various types of blood cells was first recognized when cells from the bone marrow would form colonies of cells in the spleens of histocompatible recipients. The number of stem cells was determined by counting the number of colonies formed in the spleen (colony-forming units). Through the use of such techniques, it was possible to show that a very small number of stem cells could not only reproduce themselves, but also give rise to the complete spectrum of phenotypic colonies of blood cells. Less than 0.05% of the cells in the bone marrow are pluripotent hematopoietic stem cells, most of the proliferating cells are transit-amplifying cells.

The number of transit-amplifying cells in the bone marrow varies, depending on the hematopoietic cell lineage. The survival time of circulating blood cells varies from polymorphonuclear cells, which only live for a few days – to red blood cells, which may survive for many months – to selected populations of lymphocytes, which may survive for years. The majority of circulating blood cells cannot proliferate. For example, red blood cells exclude their nuclei and polymorphonuclear cells inactivate their nuclei and condense them in clumps, so that neither of these cells can be stimulated to proliferate. Because of the rapid loss of polymorphonuclear cells, the number of transit-amplifying cells belonging to the polymorphonuclear

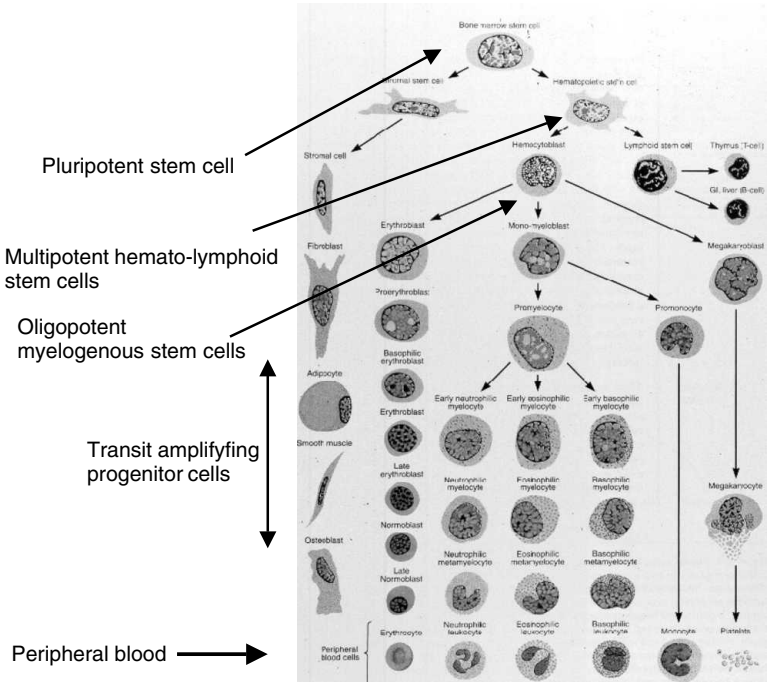

Fig. 7 Diagram of hematopoietic cell lineage. The bone marrow contains a pluripotent hematopoietic stem cell that gives rise to multipotent mesenchymal and hematopoietic lineages. The hematopoietic progenitor cell is believed to produce progeny that enter the blood cell pathway (hemocytoblast) or the lymphocytic pathway (lymphoid stem cell). The hemocytoblast is the common progenitor cell for red blood cells, white blood cells, and megakaryocytes (platelets). The white blood cell precursor (monomyeloblast) gives rise to transit-amplifying cells for monocytes (promonocytes) and polymorphonuclear cells (promyelocytes). The myelocytic series of transit-amplifying cells produces progenitors for neutrophils, eosinophils, and basophils. During this process, there is an exponential increase in numbers of cells at each stage. Thus, the totipotent stem cell is extremely rare, whereas there are enormous numbers of precursors for red blood cells and polymorphonuclear neutrophils in the bone marrow.

lineage (myelocytic series) in the bone marrow is very large (billions). Also, even though the survival time of red blood cells is much longer, there are approximately 1000 red blood cells for each white blood cell. Thus, the number of precursor cells for red blood cells is also very large. These are present in the bone marrow as transit-amplifying blast cells and their progeny at various stages of differentiation into mature polymorphonuclear cells or red blood cells.

6.3.2 Pleoplasticity of Hematopoietic Stem Cells

Until recently, the most primitive bone marrow progenitor cell was believed to be pluripotent, giving rise to all types of blood cells, including lymphocytes, red blood cells, monocytes, and megakaryocytes, as

well as a mesenchymal progenitor cell that can give rise to many other cell types, such as hematopoietic supporting stromal cells, osteocytes, adipocytes, and muscle cells. Now, it has been found that after bone marrow transplantation, the donor bone marrow cells may give rise to circulating cells that have the potential to differentiate into endothelium, muscle, liver, heart, brain (astrocytes and neurons), type I and type II pneumocytes, kidney, retina of the eye, and other organs. Serial transplantation indicates that a single bone marrow cell may be able to give rise to many different tissue types, and suggests that there must be a common precursor not only for the stromal and hematopoietic lineages but also for other germ layer-derived cell types. It is this putative pleopotent bone marrow cell that has stimulated the great revival of interest in adult stem cells in the last few years. The pleopotent stem cells arising from the bone marrow of adults may have just as much promise as do ESCs for stem cell therapy. However, the pleoplasticity of bone marrow stem cells remains controversial.

6.3.3 Pleopotency Controversies

There are conflicting data regarding the pleopotential of tissue stem cells, including bone marrow stem cells. For example, although it was reported that transplanted bone marrow stem cells provided new endothelium in transplant models of atherosclerosis, it now appears, after careful analysis, that the new endothelial cells were actually derived from preexisting endothelium. In a study of muscle-derived cells contributing to bone marrow, it was found that the muscle-derived bone marrow stem cells were derived from hematopoietic stem cells present in the muscle, and not from bone marrow–derived cells. In addition, *in vitro* culture of adult mouse brain or bone marrow stem cells with ESCs generates hybrid cells containing chromosomes of both adult and embryonic cells (cell fusion), and studies using a mouse injury model indicate that bone marrow–derived cells can fuse with liver cells during regeneration. On the other hand, differentiation of liver cells from bone marrow cells without fusion has been reported in other models. Injection of autologous bone marrow cells into the artery supplying a zone of infarcted heart muscle appears to increase healing by supplying nuclei through fusion of bone marrow–derived mononuclear cells *in situ* with precursors of heart muscle cells (satellite cells). However, others are unable to reproduce these findings and found no contribution of bone marrow–derived cells to heart muscle after injury.

Assuming that pleopotent bone marrow stem cells actually exist, a number of basic questions remain unanswered. Is there a single cell type in the bone marrow that is pleopotent, or are there multiple types of progenitor cells that can give rise to different cell types in other organs? There is some evidence that there is a single cell that can do it all. Does the progenitor cell normally circulate, or is it liberated from the bone marrow by humoral signals after injury? The evidence thus far is that this cell circulates normally, but its numbers may increase after injury. Are there normally progenitor cells in mature organs, such as liver or kidney, which can recirculate back to the bone marrow? Are these cells derived from the bone marrow, or can pleopotent progenitor cells be generated in differentiated organs? The ability of brain cells to become blood cells suggests that the answer to this question is yes, but recirculation of blood-derived cells to the brain and back to the bone marrow

cannot be ruled out. Can progenitor cell lines suitable for transplantation to repair damaged organs or for delivery of gene therapy be derived from bone marrow or other organs? Extensive culture of neural stem cells (NSCs) may be required before such cells can differentiate into blood cells, suggesting that rare transformation events may occur when cultured *in vitro* and may account for neural to blood differentiation. Answers to these questions will undoubtedly be forthcoming in the next few years.

6.4 Glandular Stem Cells

Glands consist of ducts draining collections of cells known as *acini*. During development, glands such as salivary glands, breast, pancreas, liver, and prostate arise from endodermal outpouchings that bud from the endodermal layer into the adjacent mesoderm and interact with the mesoderm to form a gland. In the adult, the epithelial cells of the gland are continually renewed from progenitor cells. For the most part, these progenitor cells are located in the basal layer of the duct and at the junction of the duct and the gland. An example of the ability of a glandular stem cell to proliferate and differentiate is the response of the breast to the stimulus of pregnancy. In the normal breast, the glandular tissue is only a duct, which terminates in a pouch of duct cells (terminal duct cells). During pregnancy, the terminal duct cells first proliferate and then differentiate into milk secreting cells. After weaning of the offspring, the glandular cells die, and the breast tissue reverts to the ductal form.

6.5 Gastrointestinal (gi) Stem Cells

The glands that line the gi tract are derived from the endodermal germ layer. They also consist of ductlike structures: the base of the gland, which is a tubular structure called the *crypt*, and the top, which forms fingerlike structures (villi) that extend up into the lumen of intestine. The progenitor cells are located near the base of the crypt (Fig. 8). These cells give rise to cohorts of approximately 40 to 60 new cells per day, which then move up the walls of the crypt to be sloughed off into the intestinal lumen in four to five days. Similar to the hematopoietic progenitor cells, the proliferating cells in the GI tract are transit-amplifying cells. The true GI stem cell most likely resides near the base of the crypt and is not actively proliferating.

6.6 Skin Stem Cells

The lineage of epidermal cells includes the most primitive skin progenitor located in the bulge of the hair follicle, bipolar stem cells in the basal layer of the stratified epithelium (basal cells), and committed transit-amplifying cells in the basal layer and in a few layers of cells above the basal layer. The basal layer is also called the *stratum germinativum* (where the dividing cells are located). The layer above is termed the *stratum spinosum*, because the intercellular bridges joining these squamous cells are visualized as spines microscopically (Fig. 9). Above this layer, there is increasing keratinization of the cells and loss of the ability to proliferate.

6.7 Neuronal Stem Cells (NSC)

Until recently, the adult brain was not believed to contain stem cells. Now, NSCs have been isolated from many parts of the central nervous system (CNS), including the forebrain subventricular

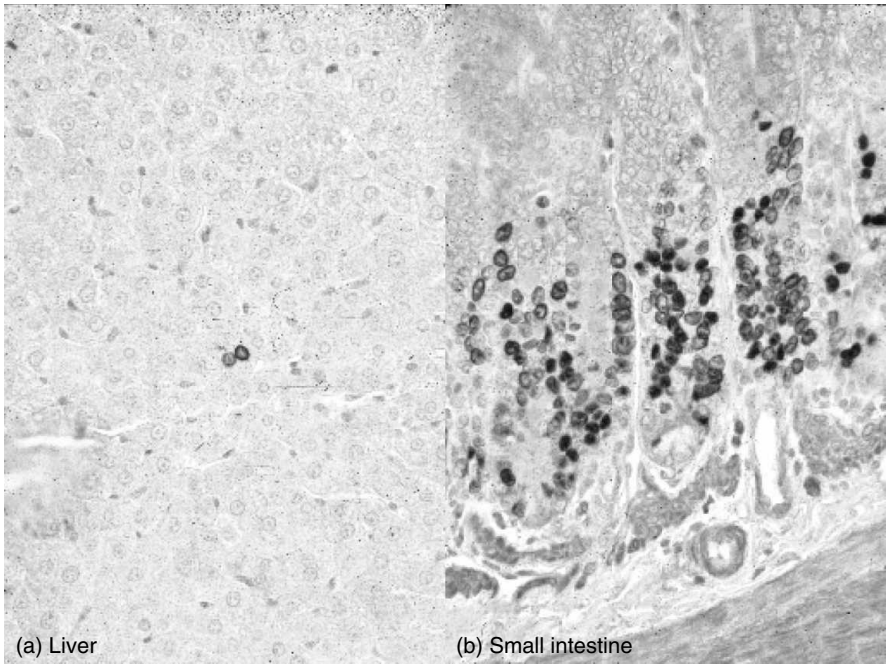

Fig. 8 Comparison of proliferating cells in liver and small intestine The dark-labeled nuclei indicate the cells that are proliferating in the liver (a) and small intestine (b) during a 24-h period. It is estimated that there are about 1 : 40 000 cells dividing in the liver at any given time, whereas millions of cells are dividing in the gi lining. The labeled cohort of cells, in panel B, will migrate up the intestinal crypt and will slough off into the intestine in four to five days.

zone, hippocampus, spinal cord, corpus striatum, septum, cortex, and optic nerve. These cells can be cultured as monolayers or as floating aggregates called neurospheres (see below). It is now clear that self-renewing NSCs not only are present in the adult brain but also can be derived from ESCs as well as other types of adult stem cells, such as hematopoietic stem cells. Multipotent neuronal stem cells are self-renewing, are able to differentiate into cells of all glial and neuronal linages, and populate developing or degenerating CNS. *In vitro* NSCs may be directed to differentiate into various cells types by addition of specific growth factors and can then be used for treatment of CNS lesions (see below).

7
Tumor Stem Cells

7.1
Embryonal Cells and Cancer

The idea that an adult human might harbor primitive ESCs was first conceived from studies on the pathology of cancer. With the invention of the microscope, pathologists by the mid-nineteenth century began to recognize that the cells that make up cancer tissues resembled embryonic tissue; Durante in Italy and Cohnheim in Austria hypothesized that tumors arose from embryonic cells present in the adult, a theory known as the embryonal rest theory of cancer. Rudolph

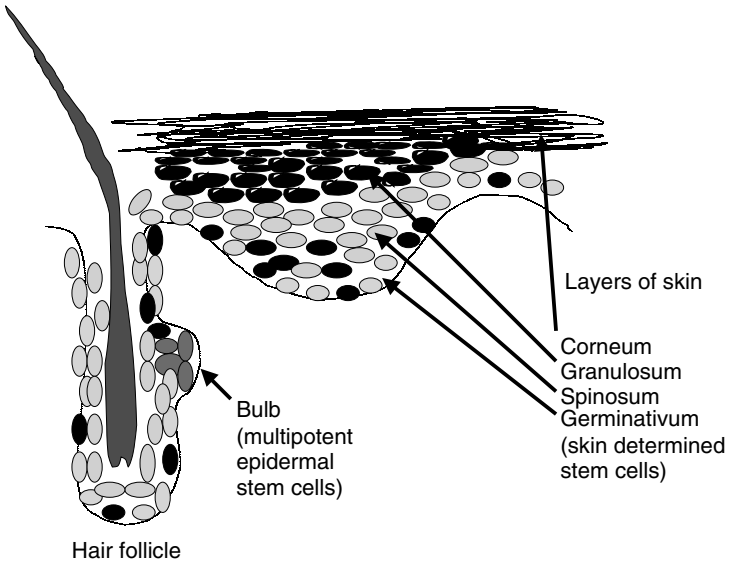

Fig. 9 Cellular layers of the skin (epidermis) and tissue renewal. Illustrated are a hair follicle and the layers of the epidermis, designated by their Latin names. The most primitive stem cells are located in the bulb of the hair follicle. When cultured *in vitro*, these cells can be passaged for many more generations than can any of the other cells derived from the epidermis. These cells give rise to various specialized appendages in the dermis, such as sweat and sebaceous glands, as well as hair follicles. The proliferating transit-amplifying cells of the skin are located in the basal layer (stratum germinativum) or in the lower layers of the stratum spinosum (indicated in black). There is then progressive accumulation of cytokeratin in the stratum granulosum associated with terminal differentiation and loss of cell structure, as the outer keratinized layer (stratum corneum) is formed. All of the cells of the skin, except for the nonproliferating resting stem cells in the basal layer, are replaced every two weeks.

Virchow observed that teratocarcinomas were made up of tissues, also found in developing embryos. The term ''dedifferentiation'' was coined by pathologists to describe this resemblance, and pathologists today still refer to the ''degree of dedifferentiation'' to grade tumors as fast growing (poorly differentiated) or slow growing (well differentiated). However, it is unfortunate that this term implies that tumors arise from dedifferentiation of mature tissues, which is unlikely.

7.2 Maturation Arrest

A cancer may arise from any cell in the body that can divide from a totipotent germ cell (teratocarcinoma) to a monopotent, tissue-determined cell. G. Barry Pierce postulated that the degree of differentiation depends on the stage of differentiation at which the majority of the cancer cells become arrested (Fig. 10). One interesting theory was that primitive sex cells (germ cells) could wander through the tissue

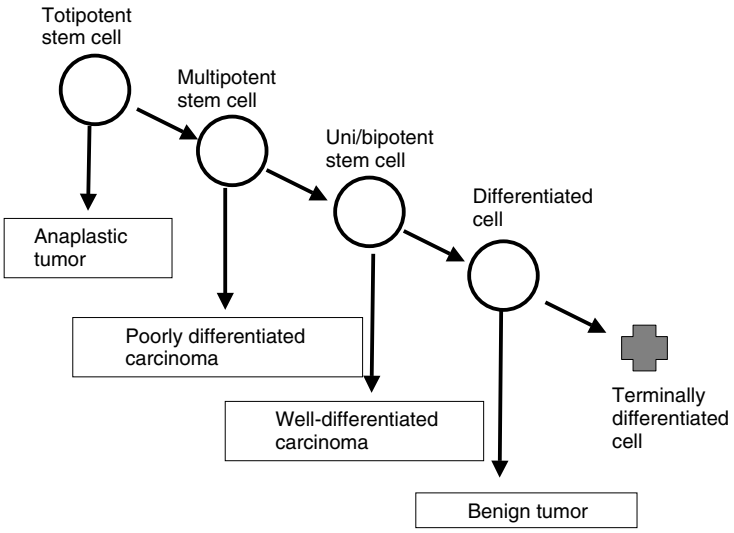

Fig. 10 Hypothesis that characteristic of a cancer is related to the stage of maturation arrest. The type of cancer in a given organ is related to the stage of determination at which the cancer arises. If it is a totipotent undifferented cell, the cancer will be anaplastic (without form). If it is a pluripotent cell, it is a poorly differentiated tumor. If it is a well-differentiated cell, it is a well-differentiated tumor. If a cell is late in differentiation, it is a benign tumor.

of the developing embryo and randomly lodge in organs other than the sex glands. In such locations, they could give rise to tumors that would express the phenotype of the tissue in which they were located, due to loss of the controlling effects of the gonadal microenvironment.

7.3 Childhood Tumors

Tumors arising in children provide clues to the relationship between ''residual'' embryonic cells and cancer. In the late 1800s, a tumor of the kidney in children was found to contain a mixture of embryonal cell types. In 1899, Wilms wrote a definitive monograph on this tumor and concluded that it arose from a fragment of the primitive undifferentiated mesodermal tissue, which normally is the analage of the kidney. Some of the cells in the tumor look like embryonal kidney and others like connective tissue, with a mixture of undifferentiated spindle cells and immature epithelial tubules. Because of this, it is also called a *mixed tumor* or *nephroblastoma*. Wilms' tumors appear to arise from embryonal cells in infants; these ''embryonic rests'' differentiate and involute with aging so that they are no longer a source of cancers after seven years of age.

A similar embryonic tumor of sympathetic ganglia, called *neuroblastoma*, originates in fetal neural crest cells of the sympathetic nervous system. These cancers have a peak age of occurrence at two years and are composed of NSCs that become more differentiated with age. In young infants, these tumors are undifferentiated and aggressive, whereas, in older children, they appear as more differentiated tumors or even as benign, well-differentiated

ganglion cells. It appears that the undifferentiated NSCs giving rise to these tumors can be differentiated into benign mature cells by the environment of the growing infant.

7.4 Leukemias as Models of Maturation Arrest

The term ''leukemia'' means white blood. It is used for cancers of the hematopoietic system, in which the number of white blood cells becomes so large that the blood appears creamy or white.

7.4.1 Gene Rearrangements and Molecular Lesions

The growth characteristics, morphology, and clinical behavior of human leukemias are related to molecular lesions caused by gene rearrangements that are found in all of the cells of the tumor, suggesting an origin in a single cell that underwent the original rearrangement. The genetic change most likely occurs in the primitive myeloid stem cells, but it is expressed when the maturing cells reach the level of differentiation at which point the translocation is activated (see Table 3 and Fig. 11). In chronic myelogenous leukemia, there is a translocation of bcr (breakpoint cluster region) to abl (Abelson tyrosine kinase), resulting in maturation arrest at the neutrophilic myelocytic series of cells. In acute myelogenous leukemia, there is constitutive activation of the IL-3 receptor, leading to continued proliferation of cells throughout the myeloid series, beginning at the level of the hemocytoblast and also including the transit-amplifying cells in the myeloid lineage. In acute promyelocytic leukemia, there is formation of a fusion protein that includes the retinoic acid receptor, which blocks differentiation at the promyelocytic stage. Rearrangement of the immunoglobulin G (IgG) promoter to the *bcl-2* or *c-myc* gene leads to expression of the product of these genes in B cells which then develop into B-cell tumors. Although the mutation may be present in all of the cells of the body, activation of the IgG promoter only occurs in B cells. Thus, manifestations of the IgG promoter rearrangements are seen in B-cell tumors.

7.4.2 Stem Cell Origin of Leukemia

The response to chemotherapy of acute leukemias also implies the involvement of a primitive stem cell, since repeated cycles of antiproliferative treatment are required. Since this therapy acts on actively proliferating cells, it would be predicted that one cycle of drug treatment would suffice to eliminate the actively

Tab. 3 Some gene rearrangements in leukemias and lymphomas.

Leukemia type	*Chromosomal rearrangement*	*Translocation*	*Function*	*Cell type*
Chronic myelogenous	t9:22	bcr/abl	Tyrosine kinase	Neutrophilic myelocyte
Acute myelogenous	t8:21	IL-3R	Tyrosine kinase	Hemocytoblast
Acute promyelocytic	t15:17	PML/RARα	Retinoic acid receptor	Promyelocyte
Burkitt's (B cell)	t8:14	IgG/myc	Transcription	B cell
B-cell lymphoma	t14:	IgG/bcl2	Blocks apoptosis	B cell

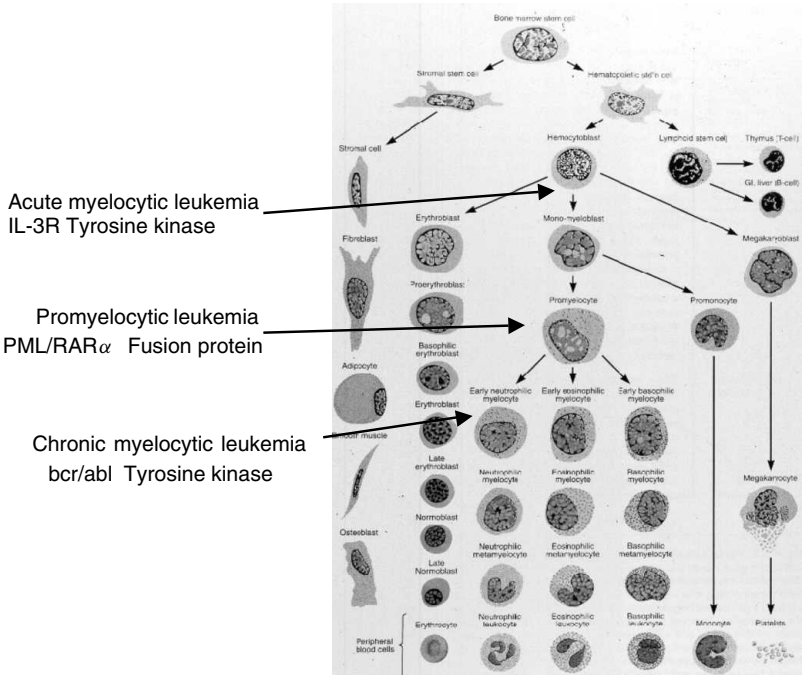

Fig. 11 Molecular defects and maturation arrest in leukemias. Gene rearrangements represent the major molecular lesions of leukemia. The examples shown here illustrate the stage of maturation at which the molecular lesions are expressed. For acute myelogenous leukemia, there is constitutive activation of the IL-3 receptor (tyrosine kinase). This causes proliferation of cells in the monomyelocytic series, as IL-3 is activated during activation of cells from the monomyeloblast through the monocyte, promyelocyte, and proerythrocyte series. For promyelocytic leukemia, there is formation of a fusion protein, which results in a block in differentiation at the promyelocytic cell. In chronic myelogenous leukemia, there is activation of abl kinase in cells of the neutrophilic series (neutrophilic myelocytes).

proliferating cells. However, the genetic damage is also present in the resting stem cells that are not proliferating at the time when the drug is given. When one cycle of treatment is completed, these resting cells will be stimulated to proliferate. When in a resting state, they will not be susceptible to treatment. Successful treatment may thus require four to five cycles of antiproliferative therapy to catch all of the leukemic cells. Even so, up to 40% of patients may require total bone marrow ablation and stem cell transplantation from a normal donor. This is most likely because the genetic lesion is present in the primitive resting stem cell in the bone marrow, which is not susceptible to antiproliferative treatment. The malignant stem cells must be destroyed by irradiation, or else the leukemia will reappear.

7.5 Epidermal Carcinogenesis and Stem Cells

Perhaps the best evidence that tumors arise from stem or progenitor cells is

provided by the two-step model of skin cancer: initiation and promotion (Fig. 12). In the classic model, benz(o)pyrene, the initiator, is painted onto the skin. This chemical binds to DNA in the skin cells, causing a permanent genetic alteration. However, cancers will not arise unless a proliferative stimulus is administered. This is provided by treating the skin with phorbol ester. Thus, the initiation induces genetic damage, and the promoter stimulates the damaged cells to proliferate, leading to cancer. Initiation must be done before promotion. If promotion is done prior to initiation, cancer will not develop. The elapse of time between initiation and promotion clearly indicates that the self-renewing stem cell is the target of initiation. Months or even years can separate initiation and promotion. Thus, in order for the tumors to grow out in this model, the initiated cells must survive from the time of initiation to the time of promotion. Given the well-established fact that all cells in the skin, except for the long-term, self-renewing stem cells, turn over completely every two to three weeks, the only way that the initiated cells could still be present if months or years elapsed between initiation and promotion would be for initiation to have occurred in the self-renewing progenitor-cell population.

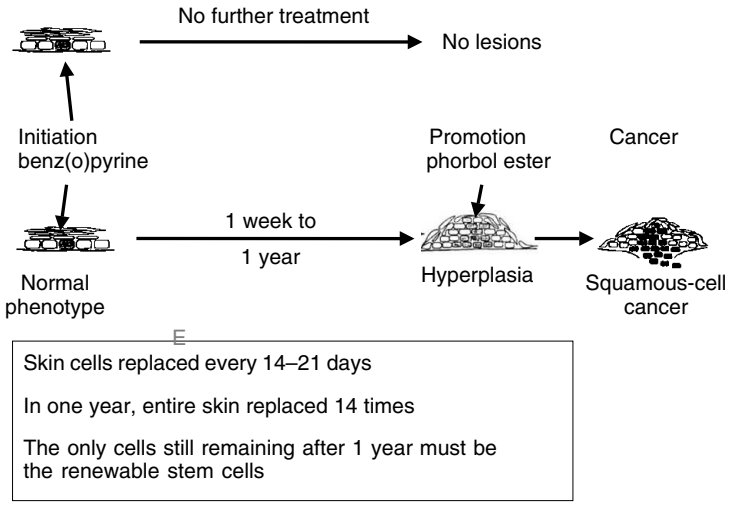

Fig. 12 Chemical carcinogenesis and the stem cell origin of skin cancer. The induction of skin cancer in animals using the initiation–promotion procedure demonstrates that skin cancers arise from stem cells. The two-step procedure of initiation and promotion employs application of a carcinogen, such as benz(o)pyrine, to the skin. Following one application, the skin appears normal and no tumors develop. Promotion is then accomplished by application of an agent that stimulates proliferation, such as phorbol ester, at the site of initiation. After promotion, tumors will appear in a short time. The critical finding is that promotion may be separated from initiation for up to a year. However, all of the transit-amplifying cells in the skin turn over within two weeks. Thus, the only cells that could remain extant from the initiation step are the self-renewing skin stem cells. Drawings modified from DiGiovanni, J. (1992) Multistage carcinogenesis in mouse skin, *Pharmacol. Ther.* **54**, 63–128.

Thus, in the initiation–promotion model for skin carcinogenesis, the initiated cell must be a self-renewing progenitor cell. If this is true, then why do the initiated cells not grow out and produce cancer during normal tissue renewal? Why is promotion required for initiated cells to grow into a cancer? It is likely that normal tissue renewal does not involve proliferation of the long-term self-renewing cells. Most normal cell renewal involves not the most primitive tissue stem cell, but rather the transit-amplifying cells. Thus, it is likely that the initiated transit-amplifying cells are not self-renewing over long periods of time, and that they eventually differentiate. The initiated cell that gives rise to cancer must be a resting stem cell that is only called upon to proliferate under the stress of promotion.

7.6 Stem cells and Adenocarcinomas

Extrapolation of the observations on the stem cell origin of carcinomas may be made to glandular organs. Exocrine glands consist of acini of glandular cells drained by a collecting duct. The key progenitor cells are located between the gland and the duct. For example, both from histologic examination of human lesions and from examination of ''preneoplastic'' lesions of experimental mouse models, breast cancers are believed to arise from basal progenitor cells located in the terminal ductular lobular unit from which the gland forms during pregnancy. Prostate cancer also arises from basal stem cells. Intestinal carcinogenesis is directed to functionally anchored stem cells in the crypt, and mutated stem cells appear to be able to spread through the mucosa by fusion of crypts, before becoming invasive. Mutation in the *adenomatous polyposis coli* gene (*APC*) is associated with increased expression of survivin, which allows expansion of crypt stem cells and development of colon cancer. Finally, mixed tumors of epithelial and mesenchymal components (carcinosarcomas) appear to arise from a common monoclonal origin. In each instance, carcinomas arise from tissue progenitor cells. There is also evidence that the cancer cells can arise from circulating stem cells that have the ability to cross basement membranes and then localize in various glandular tissues.

8 Therapeutic Applications of Stem Cells: Promises and Problems

8.1 Cellular Therapy

The results of cellular therapy of preclinical animal models of injury and disease point out both the promise and problems of using stem cells for cellular therapy. There are many models that could be presented to illustrate the need for ''Designer Therapy'', that is, the careful selection of particular cell types for specific therapies. A simplified comparison of the various types of stem cells available for cellular therapy is given in Fig. 13. As illustrations, the treatments of CNS lesions, myocardial infarcts, and diabetes will be considered.

8.1.1 Central Nervous System

Both infarcts in the brain and damage to the spinal cord have been partially corrected in mice by injection of NSCs. NSCs have the ability to migrate within the brain, site themselves in areas of brain or spinal cord damage, and restore cells in the damaged tissue with reconstitution of function – a truly remarkable capability.

	Embryonal	fetal	somatic	Tissue-determined
	Blastocyst	Neural crest	Cord blood Adult Bone marrow	Liver Pancreas etc.
No of cells	Tens	Hundreds	Millions	Hundreds
Form	Cell lines	Cell cultures	Cell isolates	Cell isolates
Potential	Totipotent	Multipotent	Pleopotent	Oligopotent
Differentiation	In vitro	In vitro/In vivo	In vivo	Differentiated
Clinical use	Experimental	Brain	Bone marrow	Experimental
Projected use for	Brain Heart	Brain Islet cells	Heart Liver	Cell replacement
Advantages	Totipotent Unlimited	Tissue directed proliferation	High numbers In vivo Selection Autotransplantation	Tissue directed
Disadvantages	Ethical issues Small number Graft rejection	Ethical issues Small number Graft rejection	Potential questioned culture limited	Small numbers difficult to get culture limited

Fig. 13 Comparison of stem cells used for cellular therapy. Each of the major sources of stem cells, embryonal, fetal (germ), and adult, has advantages and disadvantages for cell-mediated therapy. Among these, only bone marrow or cord-blood stem cells have been tested clinically. Fetal neural crest cells have been used, with some indication of success, for treatment of Parkinson's disease, but conclusive clinical trials have not been published.

The donor cells may be acquired from inner cell masses of blastocysts, from the neural crest cells of developing fetuses, or from certain areas of the adult brain (Fig. 14). The cells are cultured in special ''neural'' medium that stimulates their differentiation into neural progenitor cells. In addition, growth factors may further the differentiation of the cells into more mature types. For example, epidermal growth factor stimulates the glial differentiation required for restoration of the myelin sheath of nerves, whereas fibroblast growth factor (FGF) stimulates differentiation of nerve cells. Of these cell sources, the neural crest cells from 10.5-day gestation in the mouse have thus far been found to be the most efficient at differentiating into nerve cells; cells from 14.5-day-old fetuses are the best at differentiating into glial cells. Similar cells obtained from aborted 16- to 20-week human fetuses have been used with some success for treatment of human diseases, such as Parkinson's disease. It is very difficult to obtain enough differentiating cells from ESC cultures to use for this purpose; obtaining cells from the adult brain is not practical at this time. The use of fetal neural crest cells is also limited. The hope for the future is to obtain human ESC lines that will have the property of differentiation into neuronal or glial cells in high numbers. This will require the selection of cell lines, not available now, or alteration of cell lines through transfection with neural-specific transcription factors that will drive the cells to the desired fate.

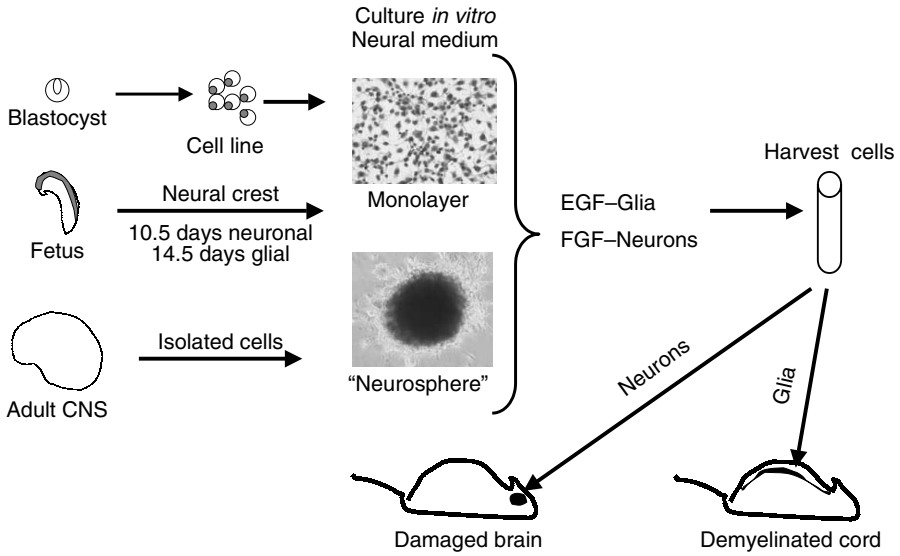

Fig. 14 Stem cell therapy of neurological deficits. Areas of necrosis in the brain, or demyelination in the spinal cord, may be repaired in mouse models by injection of stem cells that have been cultured *in vitro* and stimulated to differentiate into glial cells or neurons. This has been accomplished using ESCs, fetal neural crest stem cells, or stem cells from adult brains. Fetal neural crest cells appear to be the most effective.

8.1.2 **Type I Diabetes**

Type I diabetes is caused by the loss of insulin-secreting cells, with a consequent loss of regulation of the glucose levels in the blood and tissues, resulting in high blood glucose levels (hyperglycemia). Cellular therapy is directed toward restoring the level of insulin by transplanting insulin-secreting β-cells of the islets of Langerhans in the pancreas. Unfortunately, not only are β-cells difficult to obtain but also the desired effects of transplantation of β-cells are only achieved in less than 20% of attempts. It is predicted that stem cell precursors to β-cells contain the self-renewing cells required to maintain the number of β-cells at the level needed to maintain normoglycemia. Again, various sources of cells have been tested in preclinical animal models of diabetes, either genetically or chemically induced. These have included cells derived from adult pancreatic ducts (bipotent ductal progenitor cells), adult liver stem cells, and neonatal islet cells, as well as bone marrow cells and ESCs. Clearly, the cells more committed to the pancreatic lineage, such as neonatal islet cells and pancreatic duct-derived cells, give better results than do bone marrow stem cells or ESCs. The cells are cultured *in vitro* in the presence of high glucose, which stimulates β-cell differentiation, and are then injected into selected sites in the diabetic animal (for example, under the kidney capsule). This results in restoration of normoglycemia and prevents death due to

complications of diabetes. The take-home lesson is that cells differentiated to the pancreatic lineage are better than less-differentiated cells.

8.1.3 Heart

The severity of damage after a myocardial infarct may be lessened by injection of autologous mononuclear bone marrow stem cells into the infarct-related artery within a week after infarction. This procedure may be done in humans during coronary angioplasty after acute myocardial infarction. In a recent clinical study, the 10 patients treated with stem cells had smaller infarct areas and improved stroke volume index, left ventricular end-systolic volume, contractility of the infarct area, and myocardial perfusion of the infarct region, as compared to 10 patients in a control group not treated with stem cells.

8.2 Pleopotency or Fusion

The tantalizing findings that stem cells at various stages along the determination pathway can contribute to repair of damaged tissue have raised questions on exactly how this happens. The simplest explanation is that self-renewing stem cells are able to proliferate and differentiate into the cell types needed for repair. For example, bone marrow stem cells have been shown to contribute to many mature tissue types, including heart, liver, endothelium, lung, GI tract, and brain. Are there stem cells in the bone marrow that achieve this or are there other mechanisms? For example, the data are conflicting on the ability of bone marrow stem cells to become the smooth muscle cells of the heart. In fact, either the bone marrow cells may act through indirect mechanisms, such as by stimulation of the formation of new vessels (angiogenesis) or else mononuclear cells derived from the bone marrow fuse with regenerating heart muscle cells and contribute to there survival by adding nuclei to the muscle cells. Heart muscle cells are multinuclear, and thus it is normal for the progenitor cells of the heart (satellite cells) to fuse with other cells to form mature muscle. Cells from the bone marrow appear to do this and may increase the ability of infracted heart muscle to regenerate. The situation in the liver is also controversial. In animal models of chronic liver injury due to genetic abnormalities in the hepatocytes, transplanted bone marrow cells may fuse with residual hepatocytes and form polyploid hepatocytes that are resistant to the original injury. However, there are also convincing studies that show bone marrow cells becoming hepatocytes and gi cells without fusion. It may be that ongoing injury, with resultant inflammation and infiltration of bone marrow–derived mononuclear cells combined with damaged hepatocytes, leads to fusion of the monocytes with the hepatocytes. The contribution of the monocyte nucleus may overcome the genetic defect in the hepatocytes to allow survival.

8.3 Immune Rejection of Stem Cells

A major problem in the use of stem cells derived from embryonic or fetal tissues is the potential for such cells to be rejected when they differentiate in a histoincompatible recipient and express MHC antigens. This problem may be solved by nuclear transplantation and cloning, or by genetic manipulation of an embryonal cell line so

that it expresses the same MHC type as the recipient (see Fig. 5). However, cloning is an inefficient process and presents ethical problems, in that a human embryo must be produced to obtain the desired cells. Genetic engineering of ESC lines would be a time-consuming and expensive process. Either the cells would have to be designed specifically for the MHC of the individual recipient or else multiple cell lines expressing various MHC types would have to be produced, in order to have the cells available for any given recipient.

Histocompatibility problems are avoided through the use of autologous adult stem cells. Bone marrow transplantations are also possible across allogenic MHC barriers because the immune cells of the host are eliminated or greatly reduced by irradiation or chemical treatment, allowing the donor cells to survive. In addition, autologous progenitor cells from other tissues could be obtained from injured organs having a higher level of potential than the cells from normal organs. For example, it is possible to culture and then clone progenitor cells from animals with acute liver injury that have the potential to differentiate into other cell types, such as pancreatic cells, in addition to the expected differentiation into liver cells. It is not yet clear whether these injury-induced progenitor cells are derived from the very few progenitor cells in the mature liver, or from the circulating blood stem cells that enter the liver in larger numbers in response to the injury. In any case, there is every reason to believe that stem cell therapy is not only not limited to ESCs but is also feasible using adult stem cells. There is a lot of work to be done to find out which cells to use, how to manipulate them, and how to transplant them so as to get an optimal therapeutic result.

8.4 Seed and Soil Hypothesis

The ability of stem cells to replace tissue cells damaged by either genetic lesions or epigenetic injury is determined both by the innate potential of the stem cells and by the environment in which they are placed (seed and soil hypothesis). The ability of a stem cell to function in a given location is dependent on its potential (seed) as well as on microenvironmental signals (soil) such as cell–matrix interactions, cell–cell interactions, growth factors, hormones, and circulation gradients. Stem cells become restricted in the variety of differentiated progeny that they can produce during the determination process. For pleopotent stem cells to exist in the adult, preservation of the ESC potential must occur in some cells, the tissue progenitor cells. NSCs from the developing brain ''remember'' where they came from. On the other hand, ESCs and fetal stem cells are able to repopulate damaged neural tissue and to provide cells that will remyelinate damaged spinal cord in experimental models; bone marrow stem cells may also repair brain lesions.

8.5 Designer Therapeutic Stem Cells

Most public attention has focused on the use of ESCs for possible replacement of damaged tissue, or for use in gene therapy. This is because ESCs are capable of giving rise to any other cell type and have unlimited potential for tissue replacement. At the time of this writing, the critical and extensive work that must be done to realize the potential of ESCs is mired in ethical arguments and legal impediments. Until additional cell lines are made available, and until the studies

are accomplished, we cannot know how these cells respond to signals derived from the microenvironment of tissue culture conditions, or from the stroma of adult organs, to differentiate into the mature cell types desired. If they do respond, how many cells will differentiate, and how long will this take? In addition, the possibility that ESCs will give rise to cancer when sited out of their normal environment must be tested critically in preclinical models.

On the other hand, some form of tissue stem cell from fetal or adult individuals may be just as good as, or even better than, ESCs for some purposes. Thus, the cell of choice for treatment of a given disease may need to be selected from a specific stage along the determination pathway (see Fig. 6). In some cases, totipotent ESCs may be the optimal choice; in other cases, the tissue-determined stem cells (see Fig. 13).

There is no clear-cut answer to the question of which stem cells are optimal for any particular type of therapeutic approach. However, if we want cells to replace injured liver, or to grow up cell lines to provide liver function *in vitro* (liver bioreactors), it is logical that cells already some distance along the liver lineage pathway will be better to use than would be totipotent ESCs. Cells committed to neuronal lineages are probably better than ESCs for replacement of damaged neuronal cells. It may be possible to obtain cell lines representing cells at a particular stage of tissue determination for specific cellular therapy. In addition, these cells could be transfected with various genes under the control of promoters that are only activated by differentiated cells, so that expression of the gene is limited to the cells at the appropriate stage of differentiation. It is timely for us to develop and test the potential of designer stem cells for specific therapeutic challenges.

Keywords

Auxotroph
A mutant that is unable to grow on a simple ''minimal'' nutrient, due to its inability to make a key cellular building block, such as an amino acid or nucleic acid base, from the simple carbon source provided, for example, glucose. Such ''markers,'' for example, a requirement for histidine, or proline, or uracil are used in genetic mapping experiments. See ''complementation.''

Complementation
A mutant that makes a defective (or no) gene product can often be recognized by a requirement for a particular nutritional supplement (its auxotrophic marker). For example, a strain with a mutation in the biosynthetic pathway for histidine will not grow unless histidine is added to the simple medium. In classical genetic mapping experiments, two strains are mated and the proficient gene from one partner is passed to the recipient that has the defective gene. In this case, the nutritional requirement for histidine will disappear. This process is called ''complementation.'' In recombinant DNA experiments, when the gene that corresponds to the mutation is cloned, the event can be recognized by complementation

Cosmid
A specialized cloning vector that depends on the property of bacteriophage lambda to package selectively around 50 kb of DNA within its virus particle. The cosmid vector (typically around 10 kb is, therefore, a device that enables large (~40 kb) fragments of genomic DNA to be cloned efficiently, and is useful while preparing libraries as part of a genome sequencing project. Once the ''phage'' has been used to package the DNA, and the recombinant cosmid is introduced into *Escherichia coli*, it behaves as a plasmid.

Generalized Transduction
A change in phenotype of a recipient bacterium brought about by infection of a defective phage particle containing only donor bacterial DNA, followed by recombinational integration into the recipient's genome.

Lysogeny
The state in which a temperate phage has infected a host, which results in a stable association of the phage with the bacterium. The prophage is replicated with the bacterial genome, and is inherited by each daughter cell.

Open Reading Frame (ORF)
A nucleic acid sequence containing a series of codons without any stop codons, which may encode a protein.

Proteome
The collection of proteins made by a strain at a particular point in time. The proteome is displayed by two-dimensional electrophoresis and appears as individual spots. The technique is at its most powerful when different proteomes of the same strain are compared, to identify which proteins are upregulated or downregulated under given conditions.

Protoplast
The term given to a microbial cell after its cell wall has been removed substantially. This enables two different strains to be genetically recombined by fusion of their protoplasts in the presence of polyethylene glycol. Protoplasts are also used as recipients for naked DNA.

Secondary Metabolite
A metabolite that is made by the microorganism, often after growth has ceased – this metabolite is not essential for growth, viability, or survival of the microbe.

Transcriptome
The collection of RNA molecules present at any point in time. The transcriptome is displayed by hybridizing dye-labeled RNA to arrays of oligonucleotides, or short PCR products, which represent each gene of the organism. Each oligonucleotide or PCR product is immobilized in a fixed position on the array. A comparison of different transcriptomes indicates which genes are upregulated or downregulated under various conditions.

Sigma (σ) Factor
A protein that associates with core RNA polymerase and determines protein specificity.

Transformation/Transformant
The process by which naked DNA is introduced into a cell (or protoplast). The resulting cell is the transformant.

Transposition
The process by which a DNA element can insert itself, independent of host-cell recombination.

Transposon
A discrete DNA element capable of transposition and carrying recognizable genes, such as antibiotic-resistance markers.

Streptomyces are mycelial, soil-dwelling, differentiating bacteria that are renowned for the production of many clinically-useful antibiotics (e.g. streptomycin, erythromycin, tetracyclines, and a number of the third-generation penicillin-like antibiotics). They also make other useful metabolites (e.g. anticancer agents, immunosuppressants, antihelmintics, growth promoters, herbicides, and insecticides). Their status as simple microbial models of differentiation is well established and, because they are taxonomically related to pathogens such as mycobacteria that cause tuberculosis and leprosy (but are themselves ''safe'' organisms), they are being cited increasingly as informative models for these life-threatening pathogens. Much effort has gone into investigating the fundamental biology of *Streptomyces*. In recent years, the dissection of the architecture and regulation of antibiotic production gene clusters has been undertaken, together with studies on the regulatory circuits that control production and integrate with the signaling pathways of the differentiation processes. As clinical infections invariably develop resistance to antibiotics, there is an ongoing need to discover new drugs to combat this problem. The *Streptomyces* are viewed as a rich source of such drugs and contemporary effort, using recombinant technologies, is aimed at altering the genes for antibiotic production pathways so that they produce new, potentially useful metabolites that may keep them one step ahead of the resistance problem. Recent advances in the molecular biological techniques applicable to streptomycetes have assisted greatly in this task. The genome sequence of the model streptomycete, *Streptomyces coelicolor*, was published in 2002, followed recently by that of *Streptomyces avermitilis*. In 2004, a number of other sequencing projects were in progress, so that these resources will grow significantly in the near future. The *Streptomyces* are remarkable in that their genomes are among the largest (8–9 Mb, compared with *E. coli* at 4.6 Mb) reported so far for any bacteria. Bioinformatics, combined with postgenomic techniques such as microarrays and proteome gels, are now being used to define and characterize global gene expression under a variety of conditions. Rapid methods have been developed to create mutants for any gene, using its genome-derived DNA sequence to guide the strategy. Mutant libraries generated by random transposon insertion, are also becoming available. These aim to provide a collection of mutants in which each of the almost 8000 genes in *Streptomyces* is mutated individually. With these recent postgenomic resources building on the robust genetic systems that have been set up for *Streptomyces*, the next few years promise to be an exciting phase in our understanding of these unique bacteria.

1 Introduction

Streptomyces are members of the Gram-positive order *Actinomycetales* that includes:

- mycobacteria (the causative agents of tuberculosis and leprosy),
- corynebacteria (the causative agent of diphtheria, while other corynebacterial species are now used commercially in amino acid production),

- arthrobacters (often associated with plant pathology, but also able to degrade toxic chemicals), and
- nocardias (some of which are pathogenic).

The order *Actinomycetales* is very diverse. However, there is a convenient split, in that some members of the order are filamentous, while the others are not. The *Streptomyces* are filamentous bacteria (a feature that they share with *Nocardia*), found predominantly in the soil. They have a complex life cycle involving a sporulation phase (see later) and are remarkable for the vast range of secondary metabolites that they produce. Streptomycetes make more than 60% of known natural antibiotics, many of which are of commercial importance. They also produce secondary metabolites, which are used diversely as anticancer agents, immunosuppressants, antihelmintics, growth promoters, herbicides, and insecticides.

Thus, the streptomycetes have generated considerable interest – as model organisms to investigate microbial differentiation, as safe laboratory models (few are pathogenic) of their medically-important relations, but most importantly because of their industrial significance.

The *Streptomyces* were originally misclassified taxonomically as fungi, due to their appearance (mycelial, pigmented, and sporulating) that was reminiscent of moulds. However, they are true bacteria, displaying typical features such as bacterial cell walls, sensitivity to antibiotics targeted against bacteria, prokaryotic ribosomal structure (including 16S and 23S rRNA), and a single chromosome (albeit a linear chromosome, rather than the single circular chromosome of most other bacteria – see later). A notable feature of *Streptomyces* is the high (73%) G + C content in their DNA. Most of the other organisms have a G + C content of around 50%, and the range is 40 to 60%. It is not clear why the G + C content is so high. One theory states that because they are soil-dwelling and often found in arid desert conditions, there has been selective pressure to move away from DNA with a reasonable A + T content – which would make the organism more susceptible to damage by the ultraviolet rays of the sun.

The life cycle of *Streptomyces* involves extensive differentiation. Starting from a dormant spore, germination is followed by radial outgrowth which, on an agar plate, results in the formation of a mycelial colony. In their natural habitat, growth will often colonize soil particles. For each species, the radial growth involves branching of the hyphae in a particular pattern – the branch-to-branch distance of which, on a specific agar, is characteristic of the species and must be somehow programmed into its biology. Radial growth proceeds by apical extension of the mycelia, until some environmental cue triggers the first step in differentiation. Cues may be nutrient limitation, lack of water, or other factors that result in switching on of stress responses. Many *Streptomyces* undergo most elaborate forms of differentiation that involve lysis of the mycelia formed during radial growth and use the metabolic intermediates released from these lysed cells as building blocks to construct an aerial form of the mycelium, which reaches up and away from the radial mycelial mat. This aerial mycelium has a complex morphology that is again quite species-specific, often with helical coils that help to give the structure some rigidity. In the final phase of differentiation, the aerial mycelia septate and round off to form fresh spores. These can remain dormant and desiccated until the environmental conditions improve and a

fresh life cycle can begin again through germination.

Streptomyces coelicolor A3(2), the ''model'' streptomycete, has been studied for over 50 years – particularly through the lifelong research in the United Kingdom by Sir David Hopwood and his colleagues. The *in vivo* genetics of *S. coelicolor* were unraveled by Hopwood in the 1950s and the 1960s at the same time as the seminal discoveries on the genetics of other bacteria. Stable auxotrophs were formed easily, and they were used to construct a rudimentary linkage map. Over the years, many auxotrophic and other nutritional markers were added. Many mutants that were defective in the differentiation processes were isolated, characterized, and the positions of the genes on the linkage map were mapped carefully.

The original isolate of A3(2) produced a blue pigment, now characterized as the antibiotic actinorhodin. It was much later, in the late 1970s that attention was turned to this antibiotic, for which mutants could be recognized easily by the loss of blue pigment. In other mutant classes, there was a change in color associated with the mutation that now caused the buildup of an actinorhodin precursor or shunt metabolite. Thus, it was possible to quickly build up a collection of mutants altered in antibiotic production. It then became clear that *S. coelicolor* made a number of antibiotics: the red pigment, later identified as undecylprodigiosin; a colorless antibiotic, methylenomycin, whose production gene cluster is located on a plasmid; and a ''calcium-dependent'' antibiotic (CDA), which was only effective in the presence of the cation and later shown to have a lipopolypeptide structure that is made by a nonribosomal peptide synthase.

In 2001, when the genome sequence of *S. coelicolor* was completed, it became apparent that this model organism has the genetic potential to make over 20 different secondary metabolites, indicating the speed, power, and potential of the postgenomic approaches (see Sects. 4 and 6), compared to the classical approach. The ''classical genetic'' phase of *S. coelicolor* provided the bedrock of mutants, genetic loci, and fundamental procedures for the next phase – the ''molecular biology'' stage, involving *in vitro* techniques. The enabling methodology that resulted in the first success in cloning with *Streptomyces* was undoubtedly the ability to form and regenerate protoplasts from specially-treated mycelium. Originally developed as a tool for classical genetic analysis, whereby two strains could be genetically recombined without recourse to spore-based mating, protoplasts were fundamental to the introduction of naked plasmid DNA – enabling the first cloning experiments to be undertaken in 1980.

For the ensuing 15 years these cloning techniques, using the transformation of protoplasts, were refined substantially. Entire antibiotic pathways were cloned, dissected, and altered by mutation *in vitro*. Many of the genes identified during the classical phase of *Streptomyces* genetics were cloned by complementation and analyzed. New genes were identified and mutants of them were created by gene disruption. This was the era of laborious and meticulous characterization of the genes on an individual basis – analysis of their expression, and understanding of the complex interrelationships between them and their gene products. The construction of the ordered cosmid library of *S. coelicolor*, by Redenbach and coworkers in 1996, heralded the era of genome sequencing of *Streptomyces* (Sect. 3) and a number of other genome sequences are now completed, or projects are in progress.

These genome sequences are being annotated and bioinformatic tools are readily available for their further analysis. Gene-specific microarrays have been developed, that are now available to allow inspection of the transcriptome at any point in time or nutritional/environmental perturbation (Sect. 4). Rapid methods have now been developed to create mutants for any gene, using its genome-derived DNA sequence to guide the strategy (Sect. 6). Mutant libraries, generated by random transposon insertion, are also becoming available (Sect. 6). These aim to provide a collection of mutants in which each of the 7825 genes in *S. coelicolor* is mutated individually.

The resources discussed above can now be deployed in a number of ways. Display of the proteome of an organism at any point in time and nutritional/environmental regime (Sect. 4) provides valuable insight into the proteins being used at any instance (around 1000 of the possible 7825 will be expressed). Comparison with proteomes at other times and regimes gives further insight and, when combined with transcriptome data, provides a detailed analysis of the expression profiles of the genes. Combining this data-intensive information with parallel analyses of transcriptomes and proteomes of mutants that lack a particular gene then allows the relationship between expression of that gene with the others to be defined, and so an integrative view of the physiology of the organism results.

The next few years promise to be most exciting. We now have the genome sequences and postgenomic resources to conduct a thorough investigation of these unique bacteria. Many of the remaining questions about the integration of the morphological development with antibiotic production are sure to be answered in the near future.

Whereas these resources have been developed primarily for *S. coelicolor*, many have broad application in the industrial species, such as *Streptomyces clavuligerus* (clavulanic acid), *Streptomyces fradiae* (tylosin), *S. avermitilis* (avermectin), and *Streptomyces rimosus* (oxytetracycline). In the near future, we are also likely to see advances in our knowledge of how to exploit these industrial processes better and make them more productive.

2 The *Streptomyces* Chromosome

The precedent for chromosomal circularity established for *E. coli* during the 1960s meant that it was assumed that this was also the case for streptomycetes. In addition, early genetic studies also supported the circularity of the streptomycete chromosome. However, a circular genetic map is also consistent with having a linear chromosome. As a result of groundbreaking work by Carton Chen and Matthias Redenbach, this subsequently turned out to be the case for *Streptomyces*. Despite the inherent difficulty in determining the physical topology of this very large molecule directly, linearity was established by pulsed field gel electrophoresis of *Streptomyces lividans*, and by the ordering of the *S. coelicolor* cosmid library. Further analysis has revealed that chromosome linearity is a universal phenomenon in *Streptomyces*, as it is in related actinobacteria with similar sophisticated lifestyles. Some aspects of chromosome replication in *Streptomyces* are similar to other bacteria; for example, replication is initiated at a single origin near the chromosome center and proceeds bidirectionally. However, there is an inherent problem in replicating the ends of a linear DNA molecule, as DNA

replication can only progress in the 5′ to 3′ direction. This is because all known DNA polymerases require a 3′-OH from the adjacent ''upstream'' base to begin adding nucleotides, one at a time. In a linear chromosome, there is no free 3′-OH on one of the strands at each end. A similar problem arises in eukaryotic chromosomes, which are also linear, but here the highly-specialized telomerase complex makes a short RNA to provide that 3′-OH. Clearly, chromosomal circularity in most bacteria avoids this difficulty, as the DNA molecule does not have any ''ends.'' Streptomycetes solve the problem of the free 3′-OH by having terminal proteins (Tpg) that are covalently attached to the 5′ ends of the chromosome. They are believed to act as the primer containing the 3′-OH and this provides a solution to this ''end replication'' problem. Genes encoding Tpg have now been identified in *S. coelicolor*, *S. lividans*, *S. avermitilis*, and *Streptomyces rochei*. Recently, Tap, a telomere-binding protein, has been described; *tap* is co-transcribed with *tpg* and it interacts with both Tpg and the telomeres; both are essential for maintenance of chromosomal linearity and mutants lacking these genes invariably possess circular chromosomes. Such strains often show increased genetic instability but generally show no impairment in growth or sporulation. The implications of chromosome linearity on chromosome segregation and decatanation following replication are therefore unclear. Both ends are physically associated through an unknown interaction. The ends of the chromosome are characterized by long terminal inverted repeats (TIRs), which vary in length between 30 and 600 kb depending on the species. A comparison of TIRs from different species has revealed conserved sequences within the first 170 bp arranged as seven palindromes, and may cause the formation of DNA secondary structure important for stability of the terminal sequences. The significance of the TIRs is unclear and the overall structure of the chromosome is thought to resemble a tennis racket with the TIRs forming the handle through an association between proteins bound to each of the inverted repeats.

3 *Streptomyces* Genome Sequences

The genome sequence of the model streptomycete, *S. coelicolor* was completed in July 2001 at the Sanger Centre, Cambridge, UK. The sequenced strain, M145, is plasmid-free, and although originally derived from a prototrophic revertant of a threonine auxotroph of the wild-type strain, A3(2), M145 behaves substantially like its parent *in vivo*. The genome of *S. coelicolor* was sequenced as 325 overlapping clones. Of these, 305 were cosmids, one was an existing plasmid carrying one of the chromosome termini and 19 were selected from a set of bacterial artificial chromosomes mapped to the sequences of finished cosmid contigs by end sequencing. Each clone was fractionated into 1.4 to 2 kb fragments, prior to sequencing. The finished 325 clones formed a contiguous sequence extending from within the left TIR to the right-hand end of the genome. The genome sequence was completed by extending the incomplete left TIR with a 7-kb consensus sequence copied from the right TIR.

S. avermitilis produces the antiparasitic agent avermectin, used in veterinary medicine and for the treatment of river blindness in Africa. In contrast to

S. coelicolor, its genome was sequenced using a whole genome shotgun approach combined with cosmid end sequencing to facilitate the final assembly, and with some sequencing of entire cosmids to sequence repeated regions of DNA accurately. Several other streptomycete genome sequencing projects (Table 1) are either under way, or have been completed but are currently publicly unavailable for commercial reasons.

The localization of open reading frame (orfs) within streptomycete genome sequences is facilitated by highly-biased codon usage at the third position (mol% $G + C \approx 90$) and the two published genome sequences, for *S. coelicolor* and *S. avermitilis*, confirm this predicted consequence of the high G + C content of streptomycete DNA on codon usage. The 8 667 507 bp *S. coelicolor* genome encodes 7825 genes, while the 9 025 608 bp *S. avermitilis* genome encodes 7574. The publication of a second genome sequence has meant that it is now possible to assess the characteristic features of the streptomycete genome; it seems that the chromosomes of members of this genus have an unusual biphasic structure. *S. coelicolor* has a central core to its chromosome covering around 5 Mb of DNA and containing all genes that are unconditionally essential, such as DNA replication, transcription, and translation. In addition, it carries two arms of about 1.5 and 2.3 Mb containing conditionally-adaptive genes, such as those encoding the enzymes necessary to degrade cellulose and chitin likely to be present in the organism's natural habitat, which is soil. The *S. avermitilis* genome shows a similar division between core and arm regions.

Strong synteny exists between the core regions of the two *Streptomyces* genomes and the genomes of the two related pathogens, *Mycobacterium tuberculosis* and *Corynebacterium diptheriae*. This suggests that the streptomycete chromosome core is derived from a common actinobacterial ancestor with the arms being subsequently added by horizontal gene transfer. These organisms are superbly adapted to life in highly-variable, stressful environments. Soil is a heterogeneous environment, both temporally and spatially, which is constantly changing with respect to nutrient status, temperature, pH, and salinity. Unlike higher organisms bacteria are unable to control, to any great extent, the environment in which their cells live. Therefore, it is not surprising that this is reflected in the complexity of streptomycete genome sequences, reflecting the diversity of gene products that they have to make to cope with these changes.

The genomes of both organisms encode many new classes of proteins that are able to respond to this changing environment, such as those involved in transport and degradation of extracellular nutrients with a particular emphasis on regulation. Over 12% of proteins encoded by *S. coelicolor* are predicted to have a regulatory function (965 proteins), with a clear preference for certain regulatory groups. *S. coelicolor* encodes 65 different sigma factors responsible for controlling the promoter specificity of the RNA polymerase core enzyme. Two-component regulatory systems are found in high abundance in streptomycetes; *S. coelicolor* encodes 85 sensory kinases and 79 response regulators. The elucidation of the complex signal transduction pathways involved in the regulation of antibiotic production and morphological differentiation may now be possible through the study of previously unknown regulatory pathways in an ecologically-relevant context, rather than in the nutrient-rich environment of the laboratory.

Tab. 1 Current *Streptomyces* genome-sequencing projects. The information in this table is accurate till January 2005. For up-to-date information on the status of these and new streptomycete genome sequencing projects see www.genomesonline.org/.

Strain	***Genome size***	***Organization(s)***	***Status***
Streptomyces avermitilis MA-4680 (ATCC 31267)	9025 kb (7573 orfs)	Kitasato University, University of Tokyo, NITE, NIID, MEXT	Complete (http://avermitilis.ls.kitasato-u.ac.jp/)
Streptomyces coelicolor M145	8667 kb (7825 orfs)	Sanger Institute, John Innes Centre, BBSRC	Complete (www.sanger.ac.uk/Projects/S_coelicolor/)
Streptomyces ambofaciens ATCC 23877	8000 kb	Genoscope	Incomplete (unavailable) (more information at: www.genoscope.cns.fr/externe/English/Projets/Projet_DL/DL.html)
Streptomyces diversa		Diversa, Celera	Complete (unavailable)
Streptomyces noursei		QIAGEN	Complete (unavailable)
Streptomyces peucetius		IBR, Sunmoon University, Gene Chem Inc, MIC.	Incomplete (unavailable)
Streptomyces scabies 87–22	8100 kb	Cornell University, Sanger Institute, USDA, NSF	Incomplete (partially available at www.sanger.ac.uk/Projects/S_scabies/)

4
Streptomyces Genomics

4.1
Microarrays

Despite the large number of genes and problems of paralogous cross-hybridization compounded by the high streptomycete G + C content, the ability to monitor global gene expression in *S. coelicolor* is now achievable by microarray analysis. Two sources of microarrays are available for the *Streptomyces* research community: firstly, those produced by Stanford University (http://sncohenlab.stanford.edu/streptomyces/) in the United States and secondly, those produced by UMIST and University of Surrey, in the United Kingdom (www.surrey.ac.uk/SBMS/Fgenomics/Microarrays/index.html). The Stanford arrays were constructed by spotting between 5000 and 7000 orf-specific PCR products on glass slides. PCR products were generated from a single PCR amplification using 20-mer gene-specific primers that resulted in around 10% of the probes in the Stanford arrays being duplicates or overlapping sequences. The PCR products used to make the Surrey microarrays were originally generated by a versatile two-step procedure. The probe size designed for each orf was deliberately small in order to generate a unique product and so minimize cross-hybridization to other sequences in the genome. The first-round PCR was carried out using long PCR primers; the 3′ region of which was specific for the target gene while the 5′ region contained a universal tag sequence that allowed reamplification of the entire library with the same primer pair. In addition to the simple reamplification of the PCR products, there are other advantages with this approach. It minimizes the amount of genomic template carried onto the array, and as one of the primers can be derivatized (e.g. 5′-amidated), attachment of the PCR products to glass slides is facilitated. At present, the microarrays contain just over 7000 unique probes as well as landing lights, *Pseudomonas aeruginosa* PAO1 DNA (negative control) and rRNA (positive control). These arrays will be superseded by long oligonucleotide arrays in the near future. Both sets of microarrays have been successfully employed to investigate aspects of *Streptomyces* biology: the Stanford arrays were used to analyze dynamic changes in transcript profiles associated with developmental transition, while the Surrey arrays were used to demonstrate negative-feedback regulation of the *dnaK* operon by the DnaK chaperone machine.

4.2
Proteomics

Protein analysis by two-dimensional gel electrophoresis (2DGE) has been used with *S. coelicolor* for many years in both liquid and surface grown cultures in order to define the four stages in the life cycle of this species. Large changes in the radiolabeled protein profile obtained by 2DGE were observed when *S. coelicolor* was subjected to a variety of stresses including heat, cold, osmotic stress, and pH (http://proteom.biomed.cas.cz/). Since the completion of the *S. coelicolor* genome sequence, it has been possible to use matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) to identify many of the protein spots that show altered patterns of expression in response to stress. More extensive spot identification has led to over 10% of the theoretical proteome being mapped experimentally using 2DGE and MALDI-TOF MS

(http://dbkweb.ch.umist.ac.uk/StreptoBASE/s_coeli/referencegel/). In this study, extensive posttranslational modification was indicated as more than one protein spot per gene was observed. Subsequently, extensive posttranslational modification by N-acetylation, adenylation, and proteolytic processing was demonstrated by quadruple time-of-flight mass spectrometry (Q-TOF MS MS).

5 Genetic Tools for *In Vivo* Genetic Manipulation of *Streptomyces*

Many research groups investigating the molecular genetics of *Streptomyces* confine their activities to *S. coelicolor*, or the closely related laboratory ''workhorse,'' *S. lividans*. This is understandable, given that the genome sequence is available and postgenomic resources have been designed and developed for this application. Furthermore, there is an excellent Laboratory Manual, written by Kieser et al. in 2000, that provides comprehensive protocols and information resources for these species. However, neither strain makes a commercially-important product, so applied researchers often have to adapt and modify the existing protocols for the strains that they study. Many protocols are transportable, but some are not.

In conducting recombinant DNA experiments, the transformation efficiency (transformants per μg of DNA) of the strain under study is very important. Construction of a representative gene bank, which will give a statistically-significant number of recombinants to screen, requires a transformation efficiency of at least 10^5/μg DNA and preferentially 10^6. This is easily achievable with *S. coelicolor* and *S. lividans*, but industrial strains are often recalcitrant to formation of protoplasts and, if this can be achieved, are often fastidious in their requirements of the agar medium that they will regenerate viable mycelia from these protoplasts. The protocols need extensive modification and optimization and, for some species, an acceptable efficiency is never achieved.

Two other methods may (or may not) prove useful in introducing DNA to the strain of interest. For some streptomycetes, DNA can be introduced by electroporation. This circumvents the need to develop protocols to make protoplasts and regenerate them. Experiments can be conducted more quickly, as electrotransformed cells grow rapidly on conventional agar (often in two days), whereas protoplasts can take seven to ten days to regenerate. The original protocol, for *S. rimosus*, was published by Pigac and Schrempf in 1995. Very few examples of successful adaptation to other species have been reported subsequently, and the technique is certainly not applicable to *S. coelicolor*, or *S. lividans*. The procedure seems to work well with species that grow with short fragmented filaments, for example, *Streptomyces albus*, so that characteristic may be a benchmark to indicate the likelihood of success. Certainly, the approach should be attempted, as success carries the benefits detailed earlier.

The second method is to introduce DNA by conjugation from *E. coli*. This unlikely strategy actually works very well. The vector DNA obviously has to contain an origin of replication for *E. coli*, but it may contain either a replication origin for *Streptomyces* (so that the delivered vector replicates as an autonomous plasmid in *Streptomyces*), or no streptomycete replication origin at all (so that the delivered DNA integrates into the *Streptomyces* chromosome). The other key component of the system is that the

vector has to contain a ''transfer origin,'' *oriT*, to enable the DNA to be mobilized from *E. coli* to *Streptomyces*. The *oriT* component is a standard feature of *E. coli* plasmids that conjugate among *E. coli*. The last requirement is that the *E. coli* donor strain contains the genes necessary for promoting conjugal transfer – these genes may be resident on the chromosome, or supplied on a second plasmid. The system works extremely well for *S. coelicolor* and *S. lividans*, and has been adapted for industrial strains, such as *S. clavuligerus* and *S. rimosus*. It is now the method of choice for introducing DNA to *Streptomyces* and has superseded the protoplast route. The advantages of making all of the DNA constructs in *E. coli* and then mating them directly into *Streptomyces*, thus saving time, have been very compelling.

The final consideration while introducing DNA to *Streptomyces* is that many species have extremely active restriction systems. This is particularly true of industrial strains. Thus, DNA prepared in one host will not transform into another, as the newly-introduced DNA is recognized as ''foreign'' by the recipient and destroyed by the endogenous restriction enzymes. It is therefore crucial to test the prospective host strain to ensure that it does not restrict the DNA from the donor strain. This is most easily achieved by preparation of vector DNA from the donor strain and then transforming it into the recipient host. Vector DNA prepared from the recipient host acts as the control for this experiment. If there is no (or minimal) restriction barrier, the transformation efficiency of DNA prepared from both sources will be equivalent. A reduction in transformation efficiency when DNA from the donor is used (compared to the control when the DNA has been prepared in the recipient) indicates that the recipient has restriction enzyme activity for the DNA prepared from the donor strain. The DNA prepared in *E. coli*, or conjugated from *E. coli*, is heavily restricted by most *Streptomyces*. However, the problem may be circumvented by using a modification-deficient (*dam*, *dcm*) *E. coli* strain. Indeed, such a strain is now the preferred donor for conjugation, as detailed in the paragraph earlier.

5.1 Plasmids

Plasmids are essential components of the ''tool kit'' to develop the molecular genetics of any system. *Streptomyces* are endowed with many indigenous plasmids, so the initial cloning vectors were derived from them. Natural plasmids of *Streptomyces* fall into two categories: linear and circular.

The linear plasmids have often been termed *giant linear plasmids* (GLP's) because of their size. The best characterized example is SCP1 (*Streptomyces coelicolor* plasmid 1), which is of the order of 350 kb, but small linear plasmids have also been characterized (e.g. the 11.7-kb plasmid, pSCL1, from *S. clavuligerus*). Linear plasmids share a common feature with the chromosome in their possession of terminal proteins. As most protocols for plasmid isolation are for circular plasmids, it may well be that there are many more small linear plasmids to be discovered – simply by using the relevant protocol. Many of the GLPs are fertile and can conjugate between strains. Some integrate into the chromosome, for example, SCP1 has a preferred site of integration near the center of the linear chromosome, and then promote mobilization of chromosomal markers into the recipients by conjugation. This fertility scheme has outline similarity to the formation and mating of *Hfr* strains in *E. coli*.

Circular plasmids range from a few kilobases to many tens of kilobases in size. In the natural state, the smaller plasmids often have very high copy numbers (around 50 per cell), whereas, the larger versions are closer to unit copy number. The best characterized low-copy vector is SCP2, a 31-kb fertility plasmid of *S. coelicolor*. This natural plasmid has no selectable marker but its presence within a cell can be recognized by ''lethal zygosis'' – a phenomenon whereby a colony containing the plasmid causes a translucent zone of inhibition of growth in the lawn of surrounding cells, which do not contain the plasmid. Lethal zygosis is still a useful attribute when screening novel streptomycetes for plasmids, as both linear and circular plasmids display the phenomenon.

More advanced versions of SCP2 have been developed (e.g. pIJ922, pIJ916) by reducing the plasmid's size and introducing a selectable marker. These engineered derivatives still maintain their low copy number, and versions are available that retain the fertility/transfer genes, or have had them deleted. The utility of low-copy vectors in cloning entire antibiotic pathways has been ably demonstrated over the years. For example, the first demonstration was the cloning of the actinorhodin pathway by Malpartida and coworkers in 1984. Entire antibiotic pathways do not express in higher-copy vectors, probably because chromosomally-derived transactivating factors are then titrated out.

High-copy vectors for *Streptomyces* are almost all derived from the natural plasmid, pIJ101. Engineered versions have had extraneous DNA removed, together with the transfer functions to derive small (~4 kb) minimal replicons. Thereafter, antibiotic-resistance genes to enable selection (see Sect. 7) have been added (e.g. pIJ350) and other marker genes, such as tyrosinase (which confers a pigmented phenotype, therefore insertions within the gene are colorless, e.g. pIJ702). Transcriptional fusion versions (pIJ486 and pIJ487) have cloning sites just upstream of a kanamycin-resistance reporter gene, so that the level of resistance reflects the transcriptional potential of the cloned DNA. Lastly, there is a positive selection vector (pIJ699), in which a ''stuffer'' fragment is removed and replaced by cloned DNA. Only recombinants containing cloned DNA propagate and so cloning experiments conducted with this vector are assured 100% success of containing insert DNA.

High-copy vectors carrying highly expressed genes can often be unstable, or impair the performance of the streptomycete host. A growing realization of this problem stimulated the development of a class of integrating vectors, which use site-specific recombination to insert into the chromosome at a fixed location. Components of the actinophage ΦC31 have been adapted for this purpose. They all contain the attachment site for the phage, together with the integrase that undertakes the recombination event. The vectors may be propagated in *E. coli* and the various constructions made in this host. Then, through interspecific conjugation, the plasmid is transferred to the streptomycete, where it integrates at the attachment site. Plasmid pSET152 is the most commonly-used version of this type of vector.

5.2 Bacteriophages

Soil provides a rich source for the isolation of *Streptomyces* phages and most soils yield phages after enrichment, some

of which are specific for different species while others are polyvalent. Several phages have been developed as genetic tools for the transfer of DNA encoding biosynthetic enzymes between different streptomycete species. By far the best characterized and most useful actinophage tool is the temperate phage ΦC31 that infects both *S. coelicolor* and *S. lividans*. The frequency of lysogenization of ΦC31 is 20 to 40% and 1% of germinated lysogenic spores spontaneously release phage. The phage ΦC31 has a wide host range and infects about half of the 137 strains that it has been tested against. It is naked, showing a polyhedral head (53 nM wide), a long noncontractile tail (100 × 5 mm), a basal plate (15 nm in diameter) with at least one pin and a prominent knot between head and tail. ΦC31 is unable to transduce host DNA and adsorbs to a glycoprotein of susceptible cells by its tail. Newly germinated mycelia are especially susceptible to ΦC31, although it has been suggested that older mycelia are more efficient at adsorbing actinophages. The DNA enters the cell by an unknown mechanism in a nonpermuted linear form. The molecule then circularizes at the cohesive ends, which are then ligated to give a covalently-closed circular molecule. In the case of a lysogenic infection, the prophage is inserted in the *S. coelicolor* chromosome at gene *SCO3798*, which encodes a possible chromosome condensation protein. The establishment and maintenance of lysogeny involve the action of a single repressor protein, the reduction in concentration of which, such as by hyphal fusion, can result in zygotic induction. Induced lysogens show a latent period of 45 min, followed by a rise period pf 20 to 30 min giving a burst size of 100 to 200 virus particles. DNA replication involves a ''rolling circle'' mechanism generating concatameric molecules; the packaging of these into mature phages involves the site-specific cleavage of the concatamers into monomers. The genome of ΦC31 is 41 491 bp in length and 63.6% G + C. The arrangement of genes indicates that transcription of all genes, except one, is in the left to right organization. As in other phage genomes, early and late genes are clustered, with a further subclustering of genes according to function.

Few transducing phages have been characterized to date. SV1 and related phages, infecting the chloramphenicol-producing strains *Streptomyces venezuelae* and *Streptomyces phaeochromogenes*, were the first examples of generalized transducing phages. The prophage of ΦSF1 exists as two plasmids and is capable of transducing *S. fradiae*. Recently, a phage infecting *S. coelicolor* has been isolated, which is reported to be capable of transducing this species.

5.3 Transposons

A possible contribution to the inherent genetic instability in streptomycetes is the large number of transposons found within the *S. coelicolor* genome, as deletion of intervening sequences is a consequence of an intramolecular transposition event. There is some circumstantial evidence to support this as the terminal DNA of the *S. coelicolor* and *S. avermitilis* chromosomes contain large numbers of transposons that may generate the genetic instability associated with the chromosome ends. It is thought that these regions act as ''transposon traps'' due to the relatively low numbers of essential genes in the chromosome arms. Several streptomycete transposable elements have now been discovered by screening disrupted genes or by direct inspection of the

genomic sequence. The only compound transposon found to date in *Streptomyces* is within an unstable region of *S. lividans* and consists of two copies of IS*1373* that flank mercury resistance genes, although transposition of only one of the insertion sequences has been proven experimentally. The use of transposon mutagenesis in streptomycetes has been limited, in part because of the high target-site specificity exhibited by many indigenous streptomycete transposable elements. In addition, many transposons are delivered to *Streptomyces* on a temperature-sensitive delivery plasmid by protoplast transformation. At least in *S. coelicolor*, both protoplasting and incubation at high temperature can be mutagenic and can lead to unlinked mutations. Two indigenous transposons with a relatively low degree of target-site specificity are the phenotypically cryptic Tn*4556* from *S. fradiae* and IS*493* from *S. lividans*, and a consensus target sequence for the latter has been determined to be NgNCaNTgNNgN. More recently, two nonstreptomycete transposons have been put to use in the genus: first, the mycobacterial insertion sequence, IS*6100*, and more recently Tn*5493*, based on the Gram-negative, ''cut and paste'' transposon, Tn*5*, that also forms the basis of the *in vitro* transposition described elsewhere in this review. *In vitro* transposition has also been reported using Tn*5* and *mariner* with *S. coelicolor* DNA shotgun cloned in an *E. coli* plasmid. After localization of insertions by sequencing of the mutated plasmids, the disruptions were transferred into the *S. coelicolor* chromosome through marker replacement either by protoplast transformation or conjugation; the latter relying on an origin of transfer from *E. coli* conjugative plasmids in the cloning vector. IS*6100* was isolated as part of the compound transposon Tn*610* from *Mycobacterium fortuitum* and belongs to the IS*6* family of transposable elements, which form cointegrates as an end point of transposition. It encodes a transposase gene flanked by two 14-bp perfect inverted repeats. On the basis of the Southern hybridization studies, there is no evidence for preferred target site selection by IS*6100* in either *S. lividans* or *S. avermitilis*. A minitransposon, Tn*1792*, based on IS*6100* has also been developed and successfully used in *S. lividans* and *S. avermitilis*. The first large-scale global library of *in vivo* transposon mutants to be produced for *S. coelicolor* was generated using Tn*4560*, originally derived from Tn*4556*. This transposon had previously been used on a small scale, but it was only when it was delivered by conjugation from *E. coli* on a suicide vector that its full value became apparent. The result was a library of over 10^5 independent insertions that could easily be characterized by sequencing of ligation-mediated PCR products.

6 Genetic Tools for *In Vitro* Genetic Manipulation of *Streptomyces*

The predicted 7825 *S. coelicolor* orfs encode many proteins that represent new families as well as an expansion of existing groups. An essential prerequisite for understanding the biological function of this collection of relatively uncharacterized genes is the availability of a defined, comprehensive mutant library. In this way, the phenotypic effect of inactivating individual genes can be investigated systematically. In *Streptomyces*, the process of systematic mutagenesis has proceeded relatively slowly, due to the complexity of the protocols available to generate and identify

the location of a given mutation. While these classical approaches to the isolation and study of streptomycete mutants will continue to be used, two techniques have appeared recently that have greatly facilitated the isolation and characterization of mutants in *S. coelicolor*. Both procedures make use of the *S. coelicolor* cosmid library that provides a resource of cloned DNA covering the entire genome.

6.1 *In Vitro* Shuttle Transposon Mutagenesis

Gene disruption by *in vitro* shuttle transposon mutagenesis is achieved by adapting *in vitro* transposon mutagenesis, using a derivative of Tn*5*, to obtain insertions in representatives of the ordered cosmid library that was previously used to sequence the *S. coelicolor* genome. A transposon insertion library of a cosmid is recovered initially in *E. coli* and the location of each insertion then determined by DNA sequencing. The inclusion of an origin of transfer (*oriT*) in the transposon allows each cosmid to be subsequently mobilized into *S. coelicolor* by conjugal transfer, yielding transconjugants at high efficiency with the desired gene disruption. The minitransposon, Tn*5062* (Fig. 1), was constructed to mutagenize the *S. coelicolor* cosmid library is flanked by two Tn*5* mosaic ends and allows for *in vitro* transposition catalyzed by hyperactive Tn*5* transposase. Tn*5062* also contains a three-frame translational stop and *Streptomyces* consensus ribosome-binding site upstream of a promoterless *egfp* reporter gene to generate transcriptional fusions with the mutated gene. It also carries an apramycin-resistance gene for selection in *Streptomyces* and *E. coli* and the *oriT* origin of transfer; the latter enabling transfer of a resulting transposed cosmid by conjugation from a suitable *E. coli* donor strain to *S. coelicolor*. As the transposed cosmid does not contain a *Streptomyces* origin of replication, recovery of the transposon-borne marker depends on replacement of the wild-type gene with the disrupted cosmid-borne copy by allelic replacement and can easily be obtained by selecting for apramycin-resistant, kanamycin-sensitive transconjugants (Fig. 2). Double crossovers are obtained from over 10% of

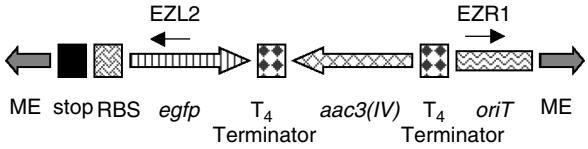

Fig. 1 Organization of Tn*5062*. The transposon consists of two inverted repeats (ME; Mosaic Ends) flanking an internal region containing the following elements: (1) a sequence consisting of translational stop codons in all three reading frames (stop); (2) a consensus streptomycete ribosome site(RBS); (3) a promoterless copy of the green fluorescent protein gene (*egfp*); (4) an apramycin-resistance gene (*aac3(IV)*) flanked by two T4 transcriptional terminators (T_4); and (5) the RK2 origin of transfer (*oriT*). Also indicated are positions of two sequencing primers, EZL2 and EZR1, used to precisely determine the location of each insertion. The sequence of Tn*5062* is deposited at EMBL (Accession number AJ566337).

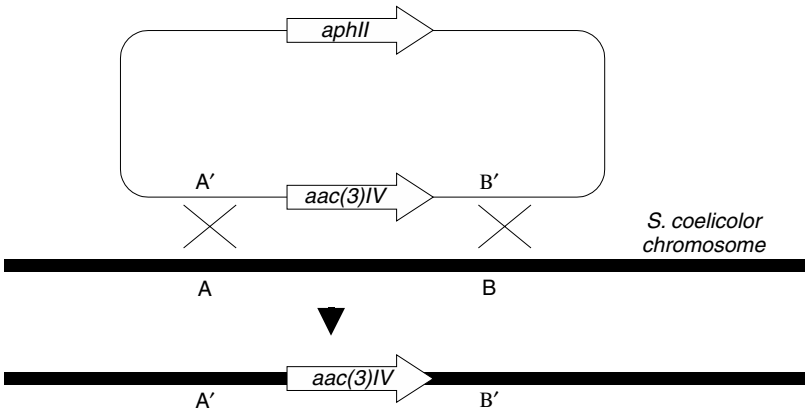

Fig. 2 Mutant generation in *S. coelicolor* after Tn*5062*- or PCR-targeted cosmid mutagenesis. Following introduction of the PCR targeting cassette or Tn*5062* (both apramycin resistant) into a cosmid that is marked with the kanamycin-resistance gene by PCR-targeted mutagenesis or *in vitro* transposition. A conjugative strain of *E. coli*, such as ET12567(pUZ8002), is transformed with the mutant cosmid. This strain is then mated with the recipient streptomycete, making use of the RK2 *oriT* region present in both cassettes, and following a double crossover between the flanking arms (A′ × A and B′ × B) of the knockout/disruption cassette, mutants in the desired gene can be isolated by selecting for apramycin-resistance and kanamycin-sensitive transconjugants.

primary transconjugant colonies due to the long flanking regions of the cosmid insertion. An appealing feature of this approach is that mutants can readily be moved into alternative genetic backgrounds and related species. Similarly, as transposition is carried out *in vitro*, an inability to recover viable transconjugants is indicative of the essential nature of that gene. Mutants are generated through gene disruption rather than deletion and as a result polar effects in many insertions are to be expected, although this may give information on domain functionality in some circumstances. *In vitro* transposon shuttle mutagenesis is, by its nature, a high-throughput technique and is designed to identify the site of the transposon insertion prior to generation of the mutant in *Streptomyces*. Eventually, this transposon library will consist of around 60 000 mutants. Many transposon insertions are located at intergenic sites or are in the wrong orientation to make use of the promoterless *egfp* reporter gene. However, sequencing DNA flanking the transposon of many thousands of transposed cosmids generated a massive amount of data, and, for this reason, a software application, Transposon Express (www.swan.ac.uk/genetics/dyson/InstallTE/), was developed to swiftly analyze a large data set of independent insertions created using Tn*5062*. This revealed a transposition target site consensus sequence of GCCCNGGGC in *Streptomyces* DNA and indicated an insertional preference for GC-rich streptomycete DNA compared to *E. coli* vector DNA. Full details of Tn*5062* insertions in the *S. coelicolor* genome are available at the *S. coelicolor* genome database, ScoDB (http://streptomyces.org.uk/). This provides access to a wide range of information relevant to *Streptomyces* research, such as

a full description of each cosmid, the annotation and gene ontologies of each gene, as well as information on primer design for PCR-targeted mutagenesis.

6.2 PCR-targeted Mutagenesis

A complementary technique based on PCR-targeted mutagenesis, known as ReDirect, was developed in parallel with *in vitro* transposon shuttle mutagenesis for use in *Streptomyces*. This method is based on generalized PCR targeting used in yeast to obtain homologous recombination via short stretches of sequence homology. In bacteria, homologous recombination at frequencies that make the technique practicable generally requires more sequence homology than can be supplied by PCR primers. However, by exploiting the recombination potential of phage λ, *E. coli* cells expressing λ red proteins can be used to enhance recombination frequencies via short homologous sequences and so generate detectable numbers of recombinants. As a result, this approach was applied to generate gene knockouts in the *S. coelicolor* cosmid library. Initially, an *E. coli* strain carrying the λ *red* genes under the control of the P_{araBAD} promoter is transformed with one of the *S. coelicolor* cosmids. In the meantime, an antibiotic-resistance gene coupled to *oriT* and selectable in both *E. coli* and *Streptomyces*, is amplified using primers whose 39 bp 5′ ends are homologous to DNA flanking a gene selected for deletion in the cosmid. This amplicon is used to transform the cosmid-carrying *E. coli* strain, where the λ *red* genes are induced with arabinose and transformants selected with the amplicon-borne resistance marker. As a result of homologous recombination between the 5′ ends of the amplicon and the *S. coelicolor* cosmid, the selected gene is deleted and the antibiotic-resistance marker is introduced into the cosmid. The equivalent region in the *S. coelicolor* chromosome can now be replaced in an analogous manner to introduction of Tn*5062* insertion (Fig. 2). This technique is less efficient than Tn*5062* mutagenesis in terms of throughput, but offers a greater degree of flexibility through the use of alternative resistance markers and reporter genes, as well as the generation of true null mutants. PCR-targeted mutagenesis has now been used to generate many hundreds of mutants in *S. coelicolor* and other strains.

7 Antibiotic Selection

More advanced vectors have been developed from naturally-occurring plasmids. They contain drug-resistance markers, which (of course) facilitates the selection of transformants. As streptomycetes are naturally-resistant to many antibiotics (e.g. the ß-lactams), a very limited number of quite unusual antibiotic-resistance genes have been used. Among these, the gene that confers resistance to thiostrepton is most popular – because most streptomycetes are sensitive to the drug. Thiostrepton acts as an antibiotic by binding to the ribosome and arresting translation. This resistance factor, cloned from thiostrepton-producer *Streptomyces azureus*, methylates host ribosomal RNA and prevents binding of the drug to the ribosome. Perhaps the most useful drug-resistance markers are those that encode resistance to antibiotics that are selective in both *E. coli* and *Streptomyces* and include *aac(3)IV* (apramycin), *aphII* (neomycin/kanamycin), *hph* (hygromycin),

aadA (streptomycin/spectinomycin), *aacI* (gentamicin), and *ermE* (erythromycin) in a decreasing order of efficacy. The first two of these selective markers are used in Tn*5062* mutagenesis and PCR-targeted mutagenesis, and as such are used for the selection of allelic replacements by mutated cosmids. pSupercos1, the vector used for generating the *S. coelicolor* cosmid library, encodes resistance to kanamycin (*aphII*) and ampicillin (*β-la*). As a result of this, and the *aac(3)IV* (apramycin) gene employed in the two *in vitro* protocols, the further use of these resistance genes is restricted in subsequent manipulations. Similarly, the most common strain used for the conjugative delivery of *oriT*-marked vectors, such as *E. coli* ET12567(pUZ8002), is already marked with chloramphenicol, tetracycline, and kanamycin resistance and may affect the choice of vectors delivered by conjugation.

8 Morphological Development

The complex life cycle of *Streptomyces* initiates with the germination of a dormant spore with subsequent hyphal emergence. Unlike unicellular bacteria, in which daughter cells separate, *Streptomyces* cells remain associated, forming long hyphal filaments that grow by apical extension. There are two kinds of cell division in *Streptomyces*: (1) vegetative septation leading to crosswall formation in substrate hyphae; and (2) sporulation septation leading to the formation of ovoid spores. Both involve the same division machinery, involving FtsQ and FtsZ, which are dispensable for vegetative growth. Differentiation involves a cascade of signaling events with nucleoid migration and septation, creating a subapical daughter cell. Septation arises through the action of the tubulin homolog FtsZ and its polymerization into the cytokinetic Z ring, and is thought to involve several membrane proteins. Exponential growth is achieved by lateral branching, allowing the *Streptomyces* colony to eventually yield radial outgrowth with formation of a mycelial mat. During this first growth phase, *Streptomyces* generate a dense multicellular network within the nutrient substrate. This apical extension and branching of vegetative hyphae enables the colonization of the media until nutrients are exhausted.

Streptomyces then form elaborately coiled, hydrophobic aerial hyphae that rise away from the plane of radial growth. A variety of extracellular factors can trigger aerial hyphae formation. Genetic dissection of the developmental programme of *S. coelicolor* reveals that at least two classes of genes are required: the *ram* genes and the bald (*bld*) genes, mutants of which are defective in the formation of an aerial mycelium and grow as smooth hairless colonies. The *ram* genes were discovered by their ability to induce rapid aerial mycelium (hence *ram*) when introduced on a low-copy plasmid in *S. lividans*. There are four *ram* genes found as an operon, *ramCSAB*, where the binding of RamR, a response regulator, to the *ramC* promoter, activates transcription. Interestingly, a *ramR* mutation prevents production of SapB and formation of aerial hyphae. SapB is a small, secreted lantibiotic-like peptide that acts as a biological surfactant, releasing the surface tension at the air–water interface and allowing the aerial hyphae to grow upright. Until recently, the product of *ramS* was unknown, with the product of *ramC* showing similarity with serine/threonine protein kinases and *ramAB* encoding components of an ATP-binding cassette transporter. However, recent studies have revealed

that SapB is derived from the product of *ramS*, after posttranslational modification by *ramC*.

Analyses of *bld* mutants allowed the detection of various proteins that have important roles during differentiation, cell–cell signaling and carbon–catabolite repression. Evidence suggests that certain bald genes are part of an organized developmental system – a signaling network in which the restoration of aerial hyphal growth is achieved through extracellular complementation. This signaling cascade involves one *bld* mutant that acts as a donor and rescues morphogenesis in the recipient to the left of a defined hierarchy, leading to erection of aerial hyphae:

$$[bldJ] < [bldK] < [bldA, bldH] < [bldG] < [bldC] < [bldD]$$

In these studies, all *bld* mutants rescue development in *bldJ* mutants, while *bldD* mutants can only be rescued by the wild-type strain. Further complementation assays indicated that once morphogenesis is restored in the acceptor strain, this backtracks and restores aerial hyphae formation in the donor, suggesting that the molecules that result from expression of these genes work in a signaling cascade for the generation of aerial hyphae. Each signal molecule then stimulates the next, so that there is finally *bldD*-induced production of SapB. The stimulation of the *bld*-signaling cascade is dependent on environmental cues such as nutrient and cell density. Catabolite repression and the accumulation of organic acids may cause many of the bald mutants to induce an acidogenic environment on glucose-based media and so prevent differentiation. Acidogenesis is the effect rather than the cause of the phenotypic expression of some *bld* mutants, particularly with the *bldA*, *bldB*, *bldG*, and *bldH* strains. It is suggested that the accumulation of organic acids by these mutants may be a consequence of limited oxygen availability in older, densely-packed substrate mycelium, thus causing a metabolic imbalance of the TCA cycle. The projection of aerial hyphae, and therefore the increase of surface area, induces oxygen availability that allows renewed metabolic activity and consequently the consumption of organic acids. Observations on the developmental signaling of *Bacillus subtilis* support this hypothesis. The *bldA* gene encodes the leu-tRNA that reads the rare UUA codon, and controls the initiation of the reproductive phase and secondary metabolism in *S. coelicolor*. Meanwhile, *bldB* and *bldD* genes encode putative transcription factors that have potential roles in phosphorylation and ADP-ribosylation, leading to the next stage of morphological development.

Development of aerial hyphae and tip extension is accompanied by a number of other physiological changes including the accumulation of polymeric storage compounds such as glycogen and the production of secondary metabolites. Stationary phase is characterized by septation and the formation of compartments that are destined to become spores. Each compartment contains at least one copy of the chromosome to ensure spore viability. Subsequently, the walls thicken and round up to form ovoid spores in a chain that is confined within a fibrous sheath that ruptures after the spore matures. Coordination of the metabolic processes with the morphological events of sporulation, especially with sporulation-associated cell division, appears to be provided by a second hierarchy of gene expression, governed initially by two σ factors. The first, σ^{WhiG}, influences sporulation in aerial mycelium. Excess σ^{WhiG} can actually

change the developmental fate of hyphae, by causing ectopic sporulation in the substrate hyphae, which normally lyse during formation of aerial hyphae. The second sigma factor, σ^F, triggers the maturation of the spore compartments, allowing rounding and thickening of the cell wall to form the characteristic gray-pigmented spores. The activity of σ^F is blocked in *whiG* mutants, thus defining part of the cascade that controls development. This highlights only 2 of the 65 sigma factors that have been identified in the *S. coelicolor* genome sequencing project. It therefore allows only a glimpse into the complex nature of initiation of aerial mycelium and spore formation.

9 Antibiotic Production

The production of antibiotics and secondary metabolites in *Streptomyces* is integrated into the complex pathway of differentiation and development, which these microorganisms pursue. Understanding how the regulatory circuits are ''wired up'' is a topic of academic interest, and also one that has substantial commercial application. A large number of mutants have now been isolated in the model genetic organism, *S. coelicolor*. Some of these mutants fail to make only one of the antibiotics within the repertoire of this organism. When such lesions do not map to the structural genes of the biosynthetic pathway, the implication is that they must be mutated in an arm of the regulatory cascade, which is specific for that pathway. Other mutants fail to make all the antibiotics, but have normal morphologies – they must have a lesion ''further up'' in the network. Yet others are blocked in some part of the differentiation process and fail to make antibiotics – they must be mutated in a central part of the regulatory cascade. Sufficient mutants have now been analyzed by molecular genetics to begin to construct testable models of the regulatory cascades. It is now well-established that cells within the mycelial mat communicate with one other using specialized small molecular-weight signaling molecules. Changes in the environment are sensed and converted to a message, which can be interpreted by the biology of the organism through cyclic phosphorylation and dephosphorylation of key proteins. *Streptomyces*, which provide an important model for such universally used ''signal transduction'' systems, are likely to be a rich source of experimental data to increase our understanding of how such systems work.

10 Optimization of Gene Expression in *Streptomyces*

The high G + C content of their DNA places some constraints on *Streptomyces* on their use of synonymous codons within protein-coding regions. The overall composition of DNA within coding regions of streptomycete DNA is 73%. However, analysis of a large number of protein-coding regions by M.J. Bibb and coworkers showed that, within the three positions of bases within each triplet, the distribution was not equal. On an average, the first base of a triplet contained DNA of 73% composition, the second base of around 50% and the third of around 95% (making the average of 73%). In pragmatic terms, when there is a choice of codons for a particular amino acid (e.g. there are six codons for leucine), those that contain a G or C in the third base will be used most frequently. Thus, for leucine, TTA

will be used very infrequently because it has no G or C, TTG will be less preferred as two of the three bases are Ts, CTA and CTT will also be less preferred because of their third bases, but CTG and CTC will be used most frequently. When it comes to the design of oligonucleotide primers based on known amino acid sequences, this feature becomes very important. For example, if a leucine is present, there is a high probability that it will be encoded by CTG or CTC rather than by the other four synonymous codons. In the design of oligonucleotide probes, this reduces the degeneracy (i.e. the number of different bases required for each amino acid) and so these much less complex oligonucleotide mixtures are more specific for streptomycete genes – giving a much better signal on hybridization. This feature may be used also in analysis of DNA sequences for protein-coding regions. If the computer is asked to scan a DNA sequence and tabulate the G + C content in each of the three positions, it is relatively easy to deduce where the likely orfs may lie.

These considerations also need to be taken into account in the design of reporter genes with which to monitor gene expression and cellular location of proteins. The array of reporter genes available for use in *Streptomyces* is more limited than those that are available in many other bacteria. ß-galactosidase is produced by all streptomycetes, and, as a result, the use of the chromogenic substrate X-GAL, is restricted to those strains in which a mutant in the gene encoding this enzyme has been created. Perhaps the most commonly used reporter gene that makes use of a chromogenic substrate in *Streptomyces* is the *xylE* gene from *Pseudomonas*, which has been used to monitor expression of many genes as a transcriptional fusion. More recently, a version of the *luxAB* cassette has been created in which all TTA codons have been replaced and the proximal few codons of both genes altered to reflect the high G + C content of streptomycete DNA. Luciferase, encoded by *luxAB*, is a very sensitive system for monitoring gene expression and, in conjunction with luminometry, provides a very sensitive and accurate system for quantifying gene expression. One drawback with this system is that the substrate, *n*-decylaldehyde, must be added exogenously and is toxic. However, when light emission is monitored by means of a 96-well luminometer, many samples can be exposed to the substrate simultaneously and a large amount of quantitative data, suitable for statistical analysis, can be generated in a short time. The best reporter system for the spatial monitoring of gene expression in *Streptomyces* is Green Fluorescent Protein. Unfortunately, the codon usage of wild-type GFP is not optimal for use in *Streptomyces*, and as a result, the enhanced fluorescence version (eGFP) is routinely used and has been used successfully to demonstrate the tissue-specific expression of various genes when used as a transcriptional fusion. Similarly, it has also been used to demonstrate the exact cellular location of proteins involved in cell division, such as FtsZ.

11 Conclusions

In the 50 years that *Streptomyces* have been studied, classical genetic systems have been developed and mutants isolated to provide the framework for the current campaign of postgenomic investigation. With the completion of the genome sequences, there has been development

in postgenomic techniques to interrogate transcriptomes and proteomes, and there has also been development of mutant libraries and rapid methods to make specific mutation and introduce them rapidly back into the chromosome; the next few years will see a quantum leap in our understanding of these important bacteria.

Keywords

Chaperonin
Ring structure that provides assisted folding to the native state, typically binding a nonnative protein in an open ring and then folding it after encapsulation, switching between the two states governed by ATP binding and hydrolysis.

Heat Shock Factor – HSF
A transcriptional regulatory factor that induces the expression of specific genes encoding the heat shock proteins and other components involved in the stress response, by binding to characteristic upstream elements.

Heat Shock Proteins
Specialized class of proteins whose abundance is thermally induced, many of which are molecular chaperones; the Hsps mediate the effector limb of the stress response, protecting proteins from misfolding and aggregation.

Molecular Chaperone
A specialized cellular protein that binds to nonnative proteins, stabilizing them or assisting their proper folding, but which is not associated with them in their final form.

Protein Aggregation
Multimolecular assembly of nonnative proteins; included are such structures as inclusion bodies and amyloid fibrils.

Stress Response
The cellular response to abnormal conditions, including abnormal temperature, oxidants, heavy metals, and organic solvents.

Unfolded Protein Response
The response of the eukaryotic secretory endoplasmic reticulum to the accumulation of unfolded proteins.

The heat shock response is a universal cellular response to stressful conditions, including not only heat exposure but also exposure to a variety of other noxious agents and conditions including oxidants, heavy metals, pH change, and nutrient starvation. In all cases, cells sense the stressful condition and respond by inducing the expression of a set of genes encoding so-called heat shock proteins (Hsps). Sensing, as reviewed below, appears in general to involve the recognition of misfolding proteins, as an immediate by-product of the stress conditions. Thus, there is a fairly uniform response mediated to the variety of different stresses. The induced heat shock proteins, whose structure and action is also reviewed here, include molecular chaperones and proteases, which act as agents that serve to protect the cell against the imposed stress. The chaperones act to stabilize misfolding proteins and assist them back to native form while in the case of proteases the action is to remove misfolded proteins by degradation. Notably, whereas such components were identified originally by their induction during stress, many of them have been subsequently observed to mediate the same actions, in many cases essential, under normal conditions. Included also in the stress-responding armamentarium are a number of components that bind to or modify nucleic acids and, while such components are at an earlier stage of study, these also may confer protection on nucleic acid containing machines such as chromatin and the ribosome.

The heat shock response can thus be conveniently considered as a ''sensing'' circuitry that mounts a transcriptional response to imposed stress, and an ''effector'' arm consisting of a variety of actions mediated by the heat shock proteins. We consider first the sensing system in bacteria and then eukaryotes, and then review the structure and action of the effectors.

1 Sensing of Protein Misfolding in Bacteria: Heat Shock and Envelope Stress Responses of *E. Coli*

Bacterial cells react to the accumulation of misfolded proteins by the induction of several different stress responses, which activate expression of heat shock genes encoding chaperones and proteases. These responses are compartment specific and therefore require the sensing of misfolded proteins in both cytosol and periplasmic space of gram-negative bacteria. Paradigms of such signaling pathways are the cytosolic heat shock response and the σ^E-dependent envelope stress response of *Escherichia coli*, both of which are described here.

1.1 The Cytosolic Heat Shock Response

The bacterial heat shock response was first described independently by Neidhardt and Yura in 1978 as reaction of *E. coli* cells to a rapid temperature upshift that allows them to survive thermal stress. Within seconds after the temperature upshift, the synthesis of at least 30 heat shock proteins (Hsps) are transiently induced, including the major chaperones (GroEL, GroES, DnaK, DnaJ, GrpE, HspG, ClpB, IbpA, and IbpB) and ATP-dependent proteases (Lon, ClpX, ClpP, HslU, and HslV) of the cytosol. The higher the temperature the longer the heat shock response and the higher the resulting Hsp levels. In case of a mild heat shock from 30 to 42 °C, the synthesis of Hsps peaks after 5 to 10 min at maximal rates of 10- to 15-fold above basal rates. The induction period is followed by an adaptation period in which the rate of Hsp synthesis decreases to a new steady state level (two to threefold above the pre-heat shock rate). The net result of this response is that the cellular levels of Hsps such as GroEL and DnaK increase by two- to fourfold upon shift to 42 °C, concomitant with an increased capacity for repair and degradation of misfolded proteins in the cytosol.

1.1.1 Inducers, Sensors, and Signals

The heat shock response is induced by a large variety of stress regimens including physicochemical factors and metabolically harmful substances (e.g. temperature upshift, pH and osmolarity changes, carbon source or amino acid starvation, oxidative stress, UV, ethanol, antibiotics, heavy metals, phage infection). Inducers have in common the potential to generate nonnative proteins, which are folding intermediates on the way to the native state, or misfolded proteins. Proteins are therefore the primary sensors of stress, and accumulation of aberrant proteins is an important signal that induces the heat shock response (Fig. 1). This scenario is strongly supported by the demonstration that the production of heterologous proteins, fusion proteins, mutant proteins, or protein fragments induces heat shock response in *E. coli*. However, the existence of additional sensors and signals such as membrane components cannot be excluded.

1.1.2 The Regulator

The heat shock regulon is positively regulated by the product of the *rpoH* gene, that is, the sigma 32 factor (σ^{32}) subunit of RNA polymerase (RNAP) which directs RNAP to promoters of heat shock genes, resulting in their transcription (Fig. 1). Heat shock promoters differ from regular promoters with respect to the – 35 region (CTTGAA, consensus), the – 10 region (CCCCATNT, consensus),

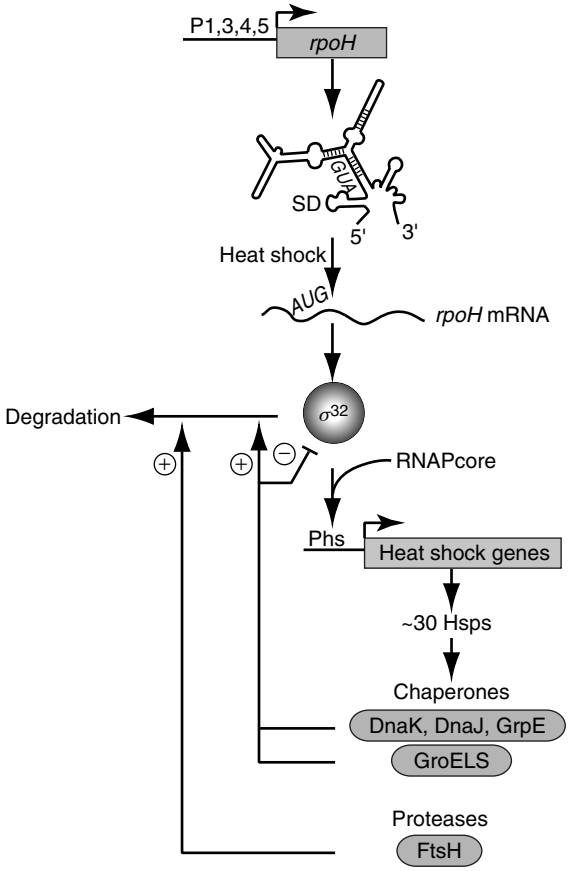

Fig. 1 Regulation of the heat shock response of *E. coli*. The positive regulator is the product of the *rpoH* gene, σ^{32}, which targets RNA polymerase to the promoters of heat shock genes. Induction of the heat shock response by temperature upshift is achieved by (1) heat-induced melting of the *rpoH* mRNA leading to its increased translation; (2) transient stabilization of the normally highly unstable σ^{32}; and (3) activation of σ^{32} allowing it to bind to RNA polymerase. The DnaK and GroEL chaperones with their cochaperones and the FtsH protease act as negative modulators of σ^{32}.

and the length of the spacer that separates these two regions (13–17 nucleotides). Some heat shock genes including *groEL, groES*, and *grpE* have additional promoter elements transcribed by the housekeeping sigma factor, which contribute to the basal levels of their expression. However, despite these additional promoters, σ^{32} is essential for growth of *E. coli* above 20 °C. Elegant genetic studies by the Yura laboratory revealed that the overproduction of a small set of chaperones with ATP-dependent protein folding activity, can rescue viability and protein aggregation defects of Δ*rpoH* cells up to 40 °C (GroELS overproduction) or even 42 °C (GroELS and DnaK, DnaJ, GrpE). These intriguing results demonstrate the essentiality of the heat shock regulon for viability of *E. coli* at most growth conditions, and the central importance of the GroEL and DnaK chaperone systems in protein quality control.

The cellular concentration of σ^{32} is very low, with 10 to 30 copies per cell at 30 °C, and is limiting for heat shock gene transcription. The temperature-induced increase in heat shock gene transcription is due to a rapid increase in the level of σ^{32} (15- to 20-fold at 5 min after shift from 30 to 42 °C), which results from increases in both synthesis and stability

of σ^{32}. Adaptation is achieved through a rapid repression of σ^{32} activity and, on a longer timescale, a decline in the levels of σ^{32}. Central to these controls of σ^{32} is the negative modulator function of chaperones and proteases.

1.1.2.1 **Control of σ^{32} synthesis.** The transcriptional regulation of *rpoH* is complex. Four promoters have been identified, three of them (P1, P4, P5) are transcribed by the housekeeping RNAPσ^{70} holoenzyme, while P3 is transcribed by RNAP containing the alternative σ^{E} (see Sect. 1.1.2), which ensures transcription of *rpoH* at extreme high temperatures at which σ^{70} is rendered inactive. Several DNA binding proteins regulate these promoters: the catabolite repression protein (CRP) activates P5; the initiator protein for DNA replication, DnaA, negatively modulates P3 and P4; the CRP–CytR protein complex negatively controls P4 and P5. This complex transcriptional regulation ensures that the levels of *rpoH* mRNA are sufficient to produce the basal levels of Hsps required for growth in a variety of environmental and metabolic conditions.

The temperature regulation of σ^{32} synthesis occurs primarily at the level of translational initiation, and relies on the formation of secondary and tertiary structures in the *rpoH* mRNA which sequester the ribosome binding site. An additional effect is that, upon increased translation during heat induction, the *rpoH* mRNA becomes stabilized and thereby accumulates. It should be emphasized that the translation regulation of *rpoH*, although contributing to the induction of heat shock gene expression after temperature upshift, does not contribute to the induction of a heat shock response at isothermic conditions, for example, following the accumulation of misfolded proteins.

The temperature-dependent structural changes in the *rpoH* mRNA require two cis acting elements in the coding sequence. A positively acting sequence element (region A) contains both the initiation site and a region of 15 nucleotides located immediately downstream of it (nucleotides +6 to +20 downstream of the AUG initiation codon). This ''downstream box'' is also found in unrelated mRNAs and acts by providing additional basepairing to the 16S rRNA, which increases translation efficiency. A negatively acting element (region B) required for temperature-dependent repression of *rpoH* translation is located between approximately +112 to +208 nucleotides downstream of the initiation codon. The repression of *rpoH* translation is mediated through the formation of secondary structures between the two elements, which occlude the translation initiation site. Consistent with this model, several mutational alterations of the *rpoH* mRNA, predicted to destabilize the base pairing between both elements, abolish the repression of *rpoH* translation. A clear correlation exists between the stability of the *rpoH* mRNA structure and the basal and heat induction of its translation, showing that intrinsic mRNA stability controls the synthesis of σ^{32}. The secondary structure formed between the two regulatory elements melts upon temperature upshift to 42 °C in the absence of any additional factor, demonstrating that the *rpoH* mRNA itself senses temperature and acts as a cellular thermometer.

1.1.2.2 **Control of σ^{32} degradation.** A second mechanism leading to the accumulation of σ^{32} during stress induction involves control of σ^{32} stability. At steady state temperature, either low or high, σ^{32} is extremely short lived *in vivo*, with a half-life of less than 1 min. Upon heat shock,

σ^{32} becomes rapidly stabilized (by eightfold upon shift from 30 to 42 °C), until during the adaptation period the stability of σ^{32} decreases again to a new steady state half-lifetime that is even shorter than at low temperature (10–15 s at 42 °C).

Degradation of σ^{32} *in vivo* is achieved mainly by the membrane associated AAA+ protease FtsH, although additional proteases such as HslUV, Lon, and ClpAP contribute to degradation as well. FtsH forms a ring-shaped oligomer with its catalytic center facing the cytosol. Degradation requires the energy of ATP, presumably for translocating σ^{32} to the catalytic center where cleavage takes place.

The molecular mechanism of the degradation process is poorly understood. A segment within the N-terminal part of σ^{32}, located within the conserved region 2, has been identified genetically as important for efficient degradation, but it is not clear whether this region constitutes a recognition site for the protease. FtsH differs from other AAA+ proteases of the *E. coli* cytosol in that it lacks a robust unfolding activity. This feature necessitates the substrate being rather unfolded before encountering FtsH. σ^{32} *per se* is indeed structurally unstable, which may facilitate its degradation. *In vitro* experiments showed that a shift of σ^{32} to heat shock temperatures within the physiological range leads to its partial unfolding, including region 2, and higher susceptibility to degradation. This suggests that the regulator of the heat shock response itself senses temperature changes. The physiological role of the structural changes within σ^{32}, leading to its increased instability at heat shock temperatures, may be to avoid unwanted overexpression of heat shock genes that are known to be inhibitory for growth.

However, the degradation process is more complex, as genetic evidence indicates a critical role for the DnaK chaperone system in efficient degradation (see the following). Whether this involves direct interaction between σ^{32} and the chaperone, perhaps by inducing a structural remodeling of σ^{32} which targets it for degradation, is unclear.

1.1.2.3 **Control of σ^{32} activity.** The control of activity of σ^{32} provides yet another layer of regulation of the heat shock response. This regulation is most apparent during a downshift of *E. coli* cells from heat shock to regular temperature, which leads to a strong and rapid repression of transcription of heat shock genes. By 15 min after a shift from 42 to 30 °C, the synthesis of GroEL decreases by 20-fold, although the level of σ^{32} decreases by only twofold. A similar repression of σ^{32} activity contributes to the regulation of σ^{32} activity at steady state conditions. This mode of regulation allows for the rapid adjustment of Hsp levels to altered requirements for chaperones and proteases, which seems crucial for cell growth.

The repression of σ^{32} activity involves the DnaK as well as the GroEL chaperone systems, both of which associate with σ^{32}. How this is achieved will be discussed in the next section.

1.1.3 The Modulators

The expression of heat shock genes in *E. coli* is regulated by the antagonistic action of the regulator σ^{32} and negative modulators (Fig. 2). Modulators are the DnaK and GroEL chaperone systems, which inactivate and destabilize σ^{32}, and to a lesser extent the FtsH protease, which is largely responsible for σ^{32} degradation. The generally accepted

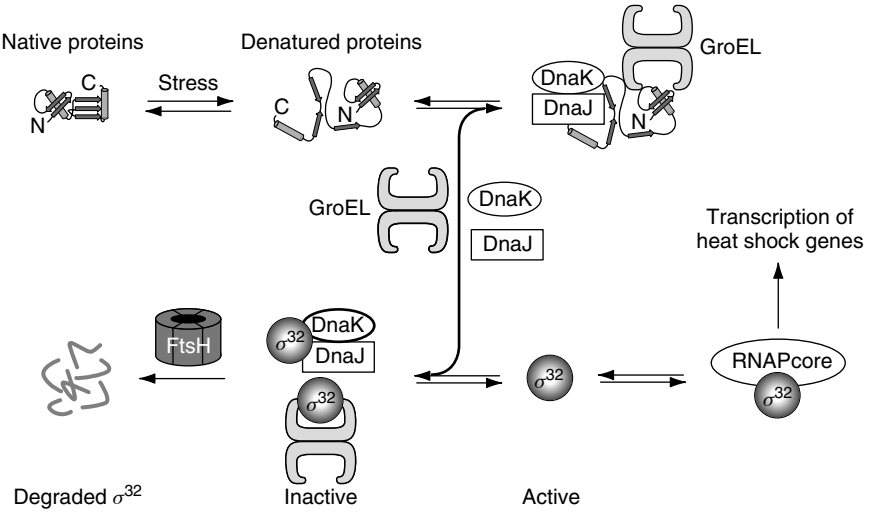

Fig. 2 Titration model of the heat shock response. DnaK and DnaJ negatively modulate σ^{32} by promoting its degradation by the FtsH protease and, through direct association, by preventing its association with the RNA polymerase core enzyme. GroEL also associates with σ^{32} resulting in negative modulation as well. Stress treatment of the cells causes accumulation of misfolded proteins in the cytosol and the sequestration of DnaK, DnaJ, and GroEL away from σ^{32}. This leads to stabilization and activation of σ^{32} and in consequence to induction of the heat shock response. Chaperone mediated repair of damaged proteins frees the chaperones to again repress and destabilize σ^{32} which reestablishes homeostasis with respect to heat shock gene expression.

model for the signal transduction pathway is that stress sequesters chaperones and proteases through binding to damaged proteins, which derepresses and stabilizes σ^{32}. Damage repair ameliorates the inducing signal and frees chaperones and proteases to shut off the heat shock response. This signal transduction is quite sensitive as it allows responses to relatively small changes in the amounts of both, chaperones and misfolded proteins. Fewer than 1500 molecules of a structurally unstable protein substrate of the DnaK system, firefly luciferase, produced per cell suffice to elicit a heat shock response. Furthermore, the artificial increase in the levels of DnaK and DnaJ, to less than 1.5-fold above wild-type levels, results in decreased level and activity of σ^{32} at intermediate temperature and faster shut off of the heat shock response; the artificial decrease in DnaK and DnaJ levels leads to opposite effects. In contrast, a decrease in FtsH levels increased the σ^{32} levels, but the accumulated σ^{32} was inactive, indicating that sequestration of FtsH alone cannot induce the heat shock response efficiently. The chaperones thus constitute the primary stress-sensing and transducing system of the *E. coli* heat shock response, while the protease may play a more indirect role.

Involvement of the DnaK system in the regulation of the heat shock response has been indicated first by genetic analysis. *dnaK*, *dnaJ*, and *grpE* mutants show an increased basal level of heat shock gene expression at 30 °C, and a delay in

the adaptation phase of the heat shock response. These alterations result from multiple defects in regulation. First, the DnaK system is crucial for degradation of σ^{32} at all temperatures, as indicated by the 10-fold stabilization of σ^{32} at 30 and 42 °C in the chaperone gene mutants. During the adaptation phase of the heat shock response, the stability of σ^{32} is also increased in *dnaK* (10-fold) and *grpE* (fivefold) mutants, but strikingly, not in *dnaJ* mutants. The weak phenotype of *dnaJ* mutants is explained by the demonstration that another DnaJ homolog existing in the *E. coli* cytosol, CbpA, can substitute for DnaJ in promoting σ^{32} degradation (and inactivation).

The second regulatory defect of *dnaK*, *dnaJ*, and *grpE* mutants is the lack of repression of σ^{32} activity following a temperature downshift (approx. 10-fold repression in wild-type cells). This defect relies on the role for the DnaK system to physically interact with free σ^{32} and to thereby inhibit its activity. DnaJ acts to target DnaK to substrates including σ^{32}, by associating with substrates and DnaK, thereby stimulating the ATP hydrolysis-driven locking in of substrates into the binding pocket of DnaK. The location of the DnaK and DnaJ binding site(s) within σ^{32} are still unclear. GrpE acts as the nucleotide exchange factor for DnaK, allowing for ADP dissociation and rebinding of ATP, which consequently leads to substrate dissociation from DnaK. σ^{32} is thereby subjected to a dynamic chaperone binding-and-release cycle, which prevents it from association with the RNAP enzyme and, consequently, from transcribing heat shock genes. It is tempting to speculate that during this cycle, the conformation of σ^{32} is altered such that it becomes more accessible for proteolytic degradation by FtsH.

Several findings indicate a role for the GroEL chaperone and its cochaperone GroES (GroELS) in the regulation of heat shock gene expression. First, the overproduction of GroELS leads to repression of σ^{32} activity, to an extent similar to the repression of σ^{32} resulting from overproduction of the DnaK system. This inhibition is alleviated by overproduction of GroELS substrates, suggesting that it is the pool of free GroELS that inhibits σ^{32}. Furthermore, the artificial depletion of GroEL results in an increased and prolonged heat shock response, presumably due to increased stabilization of σ^{32}. Finally, *in vitro*, GroEL associates with σ^{32} and inhibits its activity in transcription in synergistic action with the DnaK system.

Together, these findings indicate that modulation of the heat shock response is mediated by a network of cooperating chaperones, comprised of the two major chaperone systems of the cytosol with ''foldase'' activity, the DnaK and GroEL systems. These chaperones provide the direct link between the sensing of protein folding stress and the expression of heat shock genes, and act in concert with the direct temperature sensing by the *rpoH* mRNA, which does not involve the action of proteinaceous factors.

1.2 THE σ^{E}-dependent Envelope Stress Response

Gram-negative bacteria have a complex cell envelope composed of an inner membrane, an outer membrane, and a peptidoglycan-containing periplasmic space located in between. The periplasmic space constitutes a unique cellular compartment with respect to protein folding. First, it is exposed to strong variations in environmental conditions, in particular,

through the existence of porins in the outer membrane (OMPs), which allow the influx of ions, nutrients, osmolytes, as well as of harmful substances. Second, it is an oxidizing milieu, permitting the formation of disulfide bonds, both within and between proteins. Third, it lacks ATP and, consequently, the classical ATP-dependent chaperones of the cytosol. These features necessitate the existence of a unique set of periplasmic chaperones, folding catalysts and proteases, and a system that allows to adjust this set of folding proteins to the requirements of this compartment.

E. coli has two partially overlapping stress responses reacting to protein misfolding in the envelope, one directed by the alternative σ factor σ^E, and a second response regulated by the CpxAR two-component system. The primary function of the Cpx pathway is to control the biogenesis and structural integrity of surface structures such as bacterial pili, and to detect the attachment of the bacterial cell to surfaces. The primary function of the σ^E pathway is to counteract folding defects of outer-membrane proteins and presumably other proteins of the periplasm. The σ^E pathway is presented here in more detail as a paradigm for the sensing and transmembrane signaling of protein folding stress.

The σ^E-dependent envelope stress response (also referred to as *extracytoplasmic stress response*) was first discovered by C. Gross and coworkers in 1993 by the demonstration that excessive amounts of unfolded OMPs induce activation of the alternative σ^E subunit of RNAP. This sigma factor controls the expression of at least 11 genes, including genes encoding periplasmic folding catalysts, chaperones, and proteases, and also genes involved in biogenesis of the lipopolysaccharide (LPS) constituent lipid A and a number of lipoproteins. Among the first σ^E-controlled genes identified is *htrA* (*degP*), which encodes a periplasmic stress protein that undergoes a temperature-controlled switch from chaperone to protease activity (see Fig. 18 and text). In addition, σ^E mediates the expression of *rpoH* at very high temperatures (45–50 °C), thereby providing a regulatory link between the heat shock response and the cell envelope response. Historically, this role in the transcription of *rpoH* led to the discovery of σ^E by the C. Gross laboratory in 1989, a novel sigma factor without assigned regulon.

The σ^E pathway is induced rapidly upon shift of the cells from 30 to 43 °C, leading to 2- to 2.5-fold increased rates of synthesis of the gene products of the regulon. The rates of synthesis stay at these elevated levels, in contrast to the cytosolic heat shock response that readily enters an adaptation phase during which Hsp synthesis declines. Only when the cells are returned to pre-heat shock temperature do the rates of synthesis of the stress proteins drop rapidly to levels below those observed during steady state growth (e.g. 20-fold decline of DegP synthesis at 15 min after temperature downshift), finally reaching steady state levels.

1.2.1 Inducers, Sensors, and Signals

The σ^E-regulated envelope stress response is induced by several different stress regimen including temperature upshift, hyperosmotic stress, and ethanol treatment. The accumulation of unassembled OMPs (outer-membrane porin proteins) such as OmpF, OmpC, OmpT, and OmpX generates a particularly strong signal. Notably, OMPs only induce the response if they accumulate as unfolded species in the periplasmic space on their route, productive or abortive, to the outer membrane.

They do not generate a signal once they are properly assembled into their native oligomeric states in the outer membrane, or when they fail to be translocated across the inner membrane, remaining cytosolic. The σ^E pathway is induced, for example, by mutational alterations in OmpC, which prevent its insertion into the outer membrane and lead to its periplasmic accumulation. A complementary finding is that the reduced production of OmpC and OmpF leads to decreased expression of the genes controlled by the pathway.

The σ^E pathway primarily monitors assembly defects of outer-membrane proteins. However, misfolding of other proteins is also presumably sensed by this pathway as it is induced in mutants lacking periplasmic folding catalysts and disulfide bond oxidoreductases, in mutants producing a defective LPS, and in mutants producing unfolded variants of the periplasmic maltose binding protein MalE.

1.2.2 The Regulator

σ^E belongs to the large extracytoplasmic functions (ECF) subfamily of sigma factors, which are defined according to their ability to activate the expression of extracytoplasmic functions. σ^E confers to RNAP a promoter specificity – GAACTT, – 35 consensus; TCTGA, – 10 consensus; 16-bp spacer between both promoter regions – that is unique for promoters driving the expression of stress envelope genes. The *rpoE* gene encoding σ^E is organized in an operon together with the *rseA, rseB*, and *rseC* genes, at least two of which (*rseA, rseB*) are involved in the regulation of σ^E activity (see the following). The expression of *rpoE* and the other genes of this operon is autoregulated; a temperature upshift causes a slight (1.2- to 1.5-fold) increase in transcription of the *rpoE* gene.

It appeared at first that σ^E is nonessential for growth at temperatures below 40 °C. However, recent work established that σ^E is an essential sigma factor at all growth temperatures, but that genetically unlinked suppressor mutations arise with high frequency, which allow cell survival at lower temperatures. The σ^E regulon therefore provides essential functions related to protein folding and turnover in the cell envelope.

1.2.2.1 Signal transduction across the membrane – control of σ^E activity by RseA, RseB, and RseC.

The sensing of misfolded proteins accumulating in the periplasm and outer membrane of gram-negative bacteria requires the transduction of these signals to the cytosol (Fig. 3). The key protein that relays the stress signals across the inner membrane and ultimately leads to activation of periplasmic chaperone and protease genes is RseA, a protein located in the inner membrane that acts as antisigma factor for σ^E. RseA is composed of a single membrane spanning segment, an N-terminal cytoplasmic domain, and a C-terminal periplasmic domain. With its cytoplasmic domain, RseA associates with σ^E thereby sequestering it away from RNAP. The determination of the atomic structure of the inhibitory complex between σ^E and the cytoplasmic domain of RseA elucidated the molecular basis for the sequestration. RseA is sandwiched between the two major domains of σ^E and acts by sterically occluding the two sites in σ^E, which are most important for association with RNAP. With its periplasmic domain, RseA binds the periplasmic protein RseB, a minor negative regulator of σ^E. Intriguingly, all three components of this protein complex (σ^E, RseA, RseB) are coregulated and induced during the stress

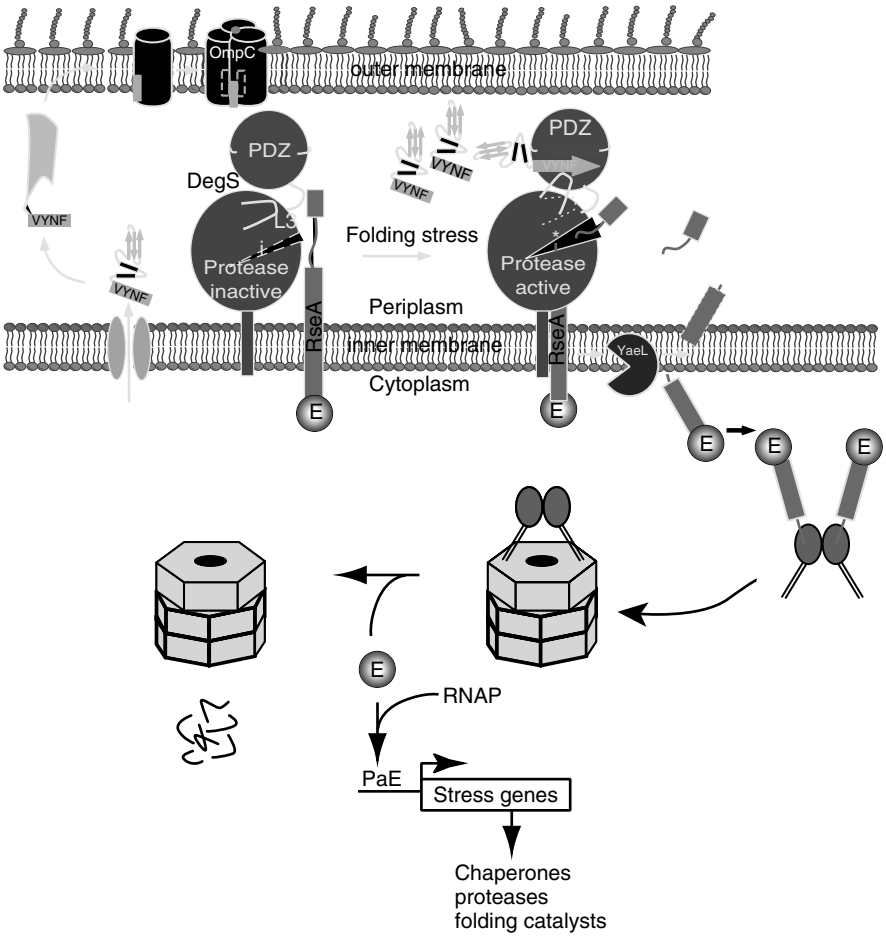

Fig. 3 σ^E-regulated envelope stress response. At noninducing conditions, the periplasmic DegS protease exists in an inactive conformation. The overproduction or mutational alteration of trimeric outer-membrane porins (Omp) lead to accumulation of unassembled folding intermediates, which expose usually buried C-terminal motifs (in red). The motif residues bind to the PDZ domain of DegS by formation of an additional ß-strand (red arrow), leading to a flipping of the flexible loop L3 toward the PDZ-protease domain interface. L3 repositioning activates the catalytic center (from i to *), making it accessible for a short unstructured segment of the DegS substrate, the anti-σ^E factor RseA. Initial cleavage of RseA by activated DegS initiates a subsequent cleavage of RseA by YaeL, which releases a fragment of RseA in complex with σ^E into the cytoplasm. Subsequently the SspB adaptor of the ClpXP protease binds to the RseA fragment and targets it to degradation, ultimately releasing σ^E, which then drives expression of genes encoding periplasmic chaperones and proteases. For clarity only one subunit of the DegS trimer is depicted and the RseB modulator is omitted. This figure has been modified from Schlieker, C., Mogk, A., Bukau, B. (2004) *Cell* **117**, 417–420. (See color plate p. xxxvi.)

response. This upregulation provides an autoregulatory loop, which ensures that the response can be rapidly shutoff after damage repair.

1.2.2.2 **A proteolytic cascade derepresses σ^E.** The affinity of RseA for σ^E is very high. The K_d of the complex formed between the cytosolic fragment of RseA and σ^E is below 1 nM. This high affinity implies that the activation of the cell envelope response strictly requires the active dissociation of σ^E from RseA. The dissociation of RseA from σ^E is achieved by a proteolytic cascade involving three proteases, whose action ultimately leads to liberation of σ^E and activation of the σ^E pathway. Indeed, during all stages of the envelope stress response induced by heat shock, the rate of RseA degradation correlates with the activity of σ^E, suggesting that the degradation of RseA is the key step in the regulation of this response. The RseA half-life is 8 min at nonstress conditions, it decreases to 2 min during the induction of the stress response, and increases to >50 min during temperature downshift.

The proteolytic cascade is triggered by the accumulation of misfolded porins in the periplasm (Fig. 3). It is initiated by activation of DegS, a member of the family of HtrA (DegP) proteases. (This is an interesting example of evolutionary diversification, since the regulatory DegS protease controls expression of the homologous DegP protease of the periplasm, which, in contrast to DegS, has a broad substrate range and lacks regulatory function.) Activated DegS initially cleaves RseA at its periplasmic site, which then allows a second cleavage by the membrane-embedded metalloprotease YaeL (also termed *RseP*) at the cytosolic site of RseA. The modulator of RseA stability, RseB, may act to allow the protease YaeL to cleave RseA more efficiently. YaeL is an ortholog of the mammalian Site-2 protease, which is involved in the proteolytic regulation of the unfolded protein response (UPR) in the endoplasmic reticulum (ER) and of the expression of cholesterol biosynthesis genes.

The successive cleavage of RseA by DegS and YaeL releases the σ^E–RseA fragment complex from its association with the inner membrane. Then, a final proteolytic cleavage occurs in the cytosol, mediated by the ClpXP member of the AAA+ protease family in conjunction with the adaptor protein SspB. The adaptor SspB binds to a C-terminal stretch of residues within the RseA fragment and, through additional binding to the N-terminal domain of ClpX, brings the σ^E–RseA fragment complex to the protease. Importantly, only the RseA fragment is cleaved by ClpXP while σ^E remains intact and becomes liberated to associate with the core RNAP, enabling transcription of σ^E-controlled stress genes.

1.2.2.3 **Recognition of the stress signal by DegS.** The activation of DegS is the first decisive step in the proteolytic cascade. This step is tightly controlled by the association of unassembled OMPs via a conserved sequence motif (YXF) located at their C termini. Crystal structures of different OMPs show that in their fully assembled state, this motif is buried and therefore cannot bind to DegS. This strongly suggests that the exposure of the YXF motif within the OMPs signals folding stress. Strong support for this hypothesis comes from the finding that short peptides carrying the YXF motif bind to the PDZ domain of DegS, a widespread structural motif involved in protein interactions, and stimulate RseA degradation *in vitro*.

How might binding of the YXF peptide to the PDZ domain control the activity of the protease domain of DegS? The atomic structure of DegS revealed that it is a homotrimer, where the protease domains form the core and the PDZ domains protrude outwards, creating a funnel-like arrangement (see Fig. 18 for homologous DegP structure). In this structure, the serine protease catalytic site of DegS is in an inactive state. An active conformation results from the addition of an activating peptide resembling the C terminus of OmpC. The peptide becomes bound in a pocket of the PDZ domain close to the interface with the protease domain. The PDZ domain provides a first docking site for the activating signal peptide. Association of the activator peptide results in several important conformational changes in the protease domain. A flexible loop (L3), protruding from the protease domain is displaced by 15 Å from its previous location in the inactive form, and is stabilized by a contact to the OmpC peptide. Upon peptide association, several residues in the active site involved in substrate binding and catalysis, previously blocked or distorted in inactive DegS, become accessible for substrate binding and correctly aligned for catalysis. In addition, the activator positioning allows a flexible loop to transduce the structural information induced by ligand binding to the catalytic center, resulting in highly specific cleavage of the downstream target, RseA.

The activation of DegS through ligand binding to the PDZ domain is reversible, making it well suited to trigger a transient response that can be turned off upon alleviation of the stress signal. The reversible activation of DegS allows a flexible and fast adaptation to the stress signal amplitude, a prerequisite for a fine-tuned cellular response.

2
Eukaryotic Heat Shock Response – Heat Shock Factors

In multicellular eukaryotes, the stress-induced regulation of the heat shock response occurs, as with prokaryotes, principally by activation of a family of heat shock transcription factors (HSFs), resulting in elevated expression of the same family of heat shock effector proteins that are involved in protein homeostasis in bacterial systems (Fig. 4). The complexity of HSF-dependent regulation varies among species, with yeast, *Caenorhabditis elegans* and Drosophila expressing a single HSF gene, vertebrates expressing four HSF genes (HSF1 to 4), and plants expressing more than a dozen HSF genes.

Comparison of domain organization and sequence identity among HSF genes reveals that the overall structure is highly conserved among eukaryotes (Fig. 5a). Located at the amino terminus of vertebrate HSFs is a helix–loop–helix DNA binding domain, followed by an 80 amino acid leucine zipper heptad repeat (HR-A/B) necessary for homotrimer formation, a centrally located negative regulatory domain that serves to maintain HSFs in an inert monomeric state, another leucine zipper heptad repeat, HR-C, and a C-terminal transactivation domain (Fig. 5a). HR-C is thought to interact with HR-A/B in the inert state and becomes dissociated from it upon heat shock, allowing the formation of homotrimers. Notably, HR-C is absent from budding yeast HSF and human HSF4 and correspondingly, the HSF of budding yeast exhibits constitutive trimerization and DNA binding, unlike other HSFs, and for at least some genes it is not negatively regulated as in the other eukaryotes, apparently supporting basal transcription.

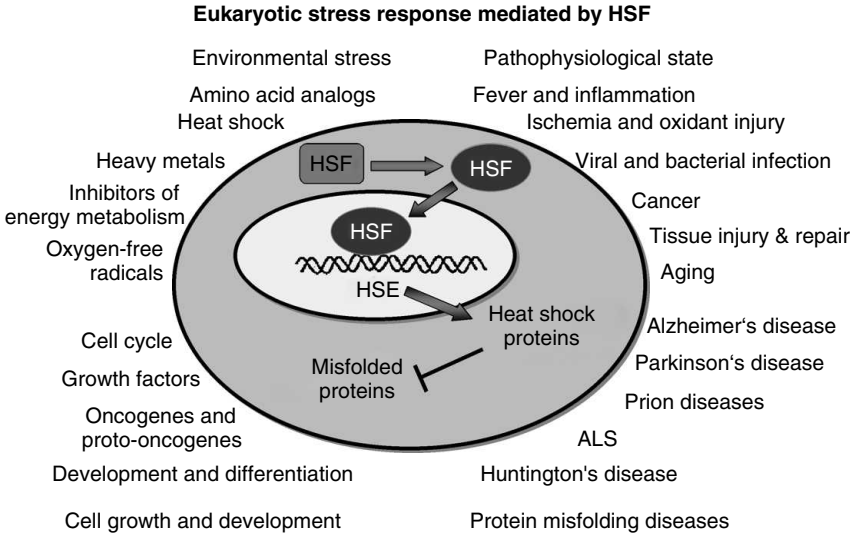

Fig. 4 Stress conditions that activate the heat shock response. Heat shock gene expression is induced by environmental and physiological stress (top left and right, respectively), by nonstressful conditions including cell growth and development (lower left), by pathophysiological states (upper right), and by protein aggregation diseases associated with the appearance of misfolded proteins (lower right). Activation of the heat shock transcription factor (HSF) leads to the transcriptional activation of heat shock genes, and the induced heat shock proteins function to prevent and repair protein damage through interaction with misfolded proteins.

HSF1 cycles between the cytoplasm and the nucleus of human cells prior to heat shock (Fig. 5b, top), and upon stress induction (Fig. 5b, right), its localization becomes nuclear and it binds to promoter elements, so-called heat shock elements (HSEs) upstream of heat-inducible genes, containing typically three contiguous inverted repeats (e.g. nTTCnnGAAnnTTCn), activating transcription (Fig. 5b, lower panels). In its nuclear location, it also rapidly forms distinctive heat shock "stress granules" that are associated with satellite repeats at chromosome 9q12, which become actively transcribed, the product message remaining associated with this locus. The nature of such heat shock transcriptional activation remains unknown.

Human HSF1 is constitutively phosphorylated in the negative regulatory domain at multiple serine residues (303, 307, and 363; Fig. 5a), but upon heat shock becomes hyperphosphorylated at these and other serine residues, for example, Ser230, associated with transcriptional activation. It is likely that additional stress-inducible phosphorylation sites will have regulatory roles for HSF1 function as suggested by mathematical modeling and sensitivity analysis of HSF1 in the human heat shock response. In addition to phosphorylation, HSF1 is also sumoylated on Lys298 in a manner that requires phosphorylation on serines 303 and 307. The role of sumoylation in HSF1 activity has not been fully established and may not be required for transcriptional activity.

Of the HSFs expressed in vertebrates, HSF1 exhibits properties that are most closely related to yeast and Drosophila

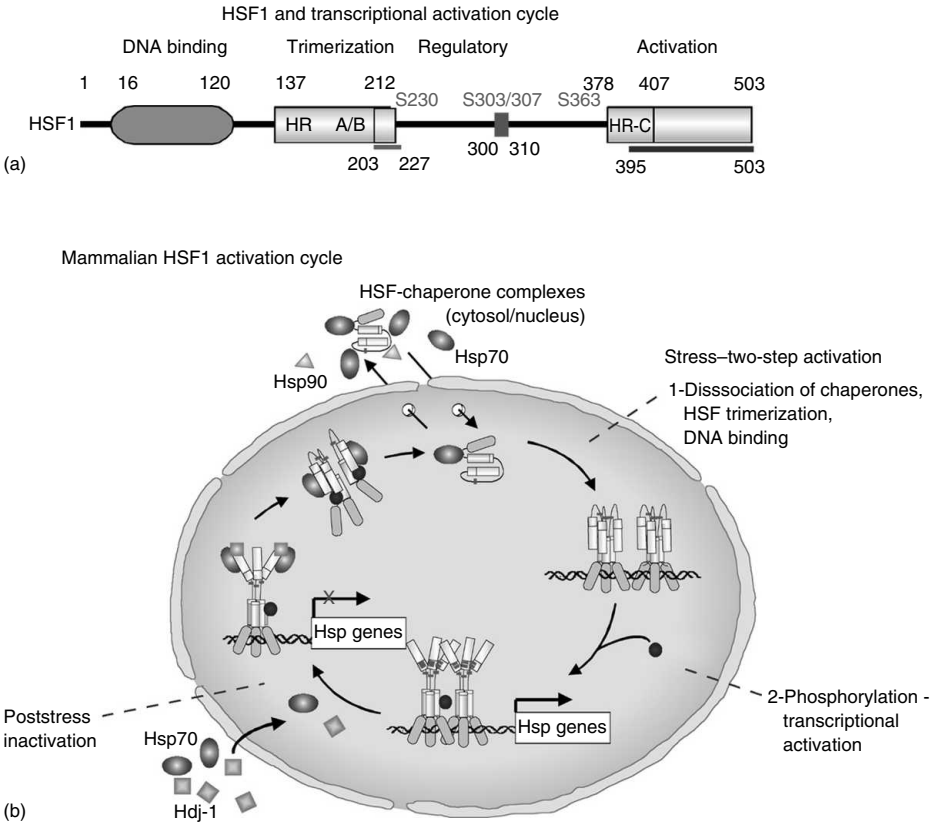

Fig. 5 Regulation of the heat shock response by HSF. (a) Domain representation of human HSF1 corresponding to the amino-terminal DNA binding domain, the heptad repeat-containing HR-A/B, the negative regulatory domain indicating sites of serine phosphorylation, the carboxyl-terminal heptad repeat, HR-C, and the transactivation domain. (b) Activation of heat shock factor (HSF1) is linked to the appearance of nonnative proteins and the requirement for molecular chaperones (e.g. hsp90, hsp70, and Hdj1) to prevent the appearance of misfolded proteins. Mammalian, Drosophila, and plant HSF1 exists in the basal state as an inert monomer (shown as intramolecularly negatively regulated for DNA binding and transcriptional activity via HR AB/C interaction). It undergoes stepwise activation, first to a DNA binding competent homotrimeric state which is transcriptionally inert, then, upon acquisition of inducible phosphorylation (green dot), to a state of activation and inducible transcription of heat shock genes. HSF1 activity is subsequently downregulated by the chaperones hsp70, hsp90, and Hdj1 which bind to HSF1 and repress its activity, and by a heat shock factor binding protein (HSBP) which binds to the region of HSF1 corresponding to the heptad repeat (not shown). (See color plate p. xxxvii.)

HSF, becoming activated as a transcription factor by various forms of stress. Notably, yeast HSF is essential for cell growth and viability, indicating that it has roles in supporting basal transcription as well as its activating role under stress. Drosophila HSF, by contrast, is dispensable to growth and viability of adult flies under nonstress conditions, but it is required during development. In mouse, deletion of HSF1

leads to placental defects, with significant prenatal mortality. Yet viable deleted animals can be obtained, but they exhibit growth retardation, female sterility, and, as expected, inability to mount a heat shock response with attendant lack of thermotolerance. Increased mortality in the face of endotoxic and inflammatory stimuli is also observed.

Recent studies in yeast employing microarray and CHIP analyses, as well as ts versions of HSF, have sought to identify the range of promoters bound by HSF and genes activated by it under heat shock conditions. More than 100 genes were both bound in their promoter regions by HSF and transcriptionally activated upon exposure to heat by at least 1.5-fold. Included were chaperones from all cellular compartments and also several components involved in ubiquitination and proteolysis, a number of components in energy and carbohydrate metabolism, as well as several to do with cell wall and cytoskeleton metabolism, and small-molecule transport. An even broader set of components was identified in microarray studies examining the entire spectrum of transcripts induced by a variety of environmental stresses, beyond regulation by HSF1, with many hundreds of transcripts upregulated. Thus, there appears to be a set of non-HSF-regulated components that can also participate in stress responses in eukaryotes. Adding to the complexity, it seems clear that there are also genes activated by HSF1, independent of its binding to classical HSE elements. A number of non-canonical elements have been identified, but for other activated transcripts there is no recognizable element.

Studies have begun to address the roles of individual HSFs where more than one is present. In avian cells, for example, the heat shock response involves two stress-activated factors, HSF1 and HSF3, which exhibit functional codependence; HSF3 null cells that express HSF1 are deficient for the heat shock response. HSF3 also interacts with other transcription factors including the oncogene Myb, via direct protein–protein interaction, through the HSF3 DNA binding domain. Myb is a growth regulated transcription factor – consequently, the interaction between Myb and HSF3 suggests genetic crosstalk between cell growth and the stress response.

One of the most provocative members of the HSF family is HSF2, originally shown to be activated in human erythroleukemia (K562) cells exposed to hemin, and subsequently detected during murine spermatocyte differentiation and embryogenesis. The stress-sensing pathway for HSF2 activation is associated with changes in the protein degradation machinery, with HSF2 DNA binding activity induced either by chemical inhibition of the ubiquitin-dependent proteasome pathway or by conditional mutations affecting the proteasome. The relationship between HSF2 activity and the protein degradative machinery reveals a requirement for Hsps, perhaps to prevent misfolding and aggregation of nonnative proteins targeted for degradation. HSF2 is also modified by sumoylation, and recently HSF2 has been shown to have a role in cell cycle control via binding to a subunit of condensin, influencing DNA compaction.

2.1 Activation of Heat Shock Factor 1

Stress-induced activation of HSF1 involves a multistep process (Fig. 5b) involving its relocalization within the nucleus, transition from an inert monomer to a trimeric DNA binding species, binding to heat

shock promoter elements, hyperphosphorylation at serine residues, and the rapid elevation in transcription of heat shock genes. Activation of HSF1 DNA binding activity is induced within minutes and attains maximal DNA binding and transcriptional activity by 20 to 30 min of continued heat shock. Thereafter, both activities attenuate to control levels within 60 to 120 min. The attenuation phase is autoregulated and requires the synthesis of high levels of chaperones that accumulate initially in the cytoplasm and relocalize to the nucleus and bind to the active trimeric state of HSF1 (Fig. 5b). The appearance of complexes between HSF1 and molecular chaperones correlates with the dissociation of HSF1 trimers from DNA and refolding of the trimer to the inert monomer. Consequently, maintenance of HSF1 in a repressed state is delicately balanced and easily disrupted. For example, transient overexpression of HSF1 is sufficient to override the negative regulators resulting in constitutive HSF1 activity. Likewise, overexpression of chaperones suppresses HSF1 activity. Specific sequences in the central negative regulatory domain of HSF1 maintain HSF1 in a repressed state; mutations cause derepression and constitutive HSF1 activity. Acquisition of HSF1 DNA binding activity alone, however, is insufficient to achieve transcription of target heat shock genes as demonstrated by certain small-molecule regulators of HSF1, such as the anti-inflammatory drug sodium salicylate, which induces DNA binding competent trimers that lack some of the posttranslational modifications associated with transcriptional activity.

The initial observations to suggest that the heat shock response is autoregulated arose from the use of amino acid analogs as inducers of the heat shock response. Treatment of Drosophila tissue culture cells with azetidine, a proline analog, led to chronic activation of heat shock gene expression. Incorporation of azetidine, or other amino acid analogs, into nascent polypeptides results in the chronic expression of misfolded proteins, led to activation of HSF1 and induction of heat shock genes. However, unlike the heat shock response itself, where attenuation is linked to the *de novo* synthesis of Hsps, the Hsp70 synthesized in amino acid analog-treated cells is likewise misfolded and nonfunctional. Consequently, in the presence of amino acid analogs, the heat shock response is chronically upregulated and does not attenuate. These observations support the idea that Hsps themselves are involved in autoregulation of the heat shock response.

Genetic evidence further supports Hsp-mediated autoregulation of the heat shock response. Overexpression of the yeast Ssa1p (cytosolic Hsp70) dampens the heat shock response, and deletion of the yeast Hsp70 genes, ssa1 and ssa2, results in an unusually high level of expression of another Hsp70 gene (*Ssa3p*) in an HSF-dependent manner. In addition, HSF itself was isolated as an extragenic suppressor of the temperature-sensitive phenotype of an Hsp70 mutant (ssa1ssa2 strain).

Biochemical evidence also supports that molecular chaperones autoregulate the heat shock response. HSF1 trimers associate with Hsp70, Hdj1 (Hsp40), and Hsp90 in ATP-sensitive complexes that can be reconstituted *in vitro*. Conditional overexpression of Hsp70 and Hdj1 results in repression of heat shock gene transcription with little or no effect on HSF1 trimer formation or DNA binding activity. Similar observations have been made for members of the DnaJ family in regulation of the heat shock response. For example, the *Saccharomyces cerevisiae*

DnaJ homolog, SIS1, negatively regulates its own expression in an HSE-dependent manner, and Drosophila Ddj1 associates with HSF1. Other chaperones including Hsp90 have been shown to interact with HSF1 or the HSF1 complex. Collectively, these results reveal that multiple chaperones are involved in the regulation of HSF1 and, moreover, that differences in specificity and kinetics may influence different aspects of HSF regulation and the heat shock response.

2.2 Pharmacological Regulation of Eukaryotic Heat Shock Response

Among the small molecules with heat shock regulatory properties are non-steroidal anti-inflammatory drugs (NSAIDs), cyclopentenone prostaglandins, serine protease inhibitors, proteasome inhibitors, the triterpene celastrol, and ansamycin benzoquinones. Salicylates and other NSAIDs have been shown to result in activation of HSF1. Moreover, treatment with sodium salicylate or indomethacin (at subthreshold concentrations) decreases the temperature threshold of the heat shock response. Exposure to salicylate or indomethacin at concentrations comparable to clinically achieved levels results in the priming of human cells for subsequent exposure to heat shock and other stresses by the enhanced transcription of heat shock genes and cytoprotection from stress-induced cell death.

Many molecules that regulate inflammation also activate HSF1, suggesting a link between inflammatory pathways and the heat shock response. The inflammatory response is induced by a cascade involving various signaling molecules including phospholipases, arachidonic acid, and prostaglandins. Some of these molecules have also been shown to induce HSF1 activity and Hsp expression. Of the prostaglandins, only the cyclopentenone prostaglandins, including PGA1, PGA2, and PGJ2, are functional in HSF1 induction. This class of prostaglandin is produced at a late stage in the inflammatory reaction, and is thought to be involved in the resolution of the inflammatory process, so cyclopentenone prostaglandins may actually be considered to be anti-inflammatory mediators.

Inhibition of protein degradation by small molecules that block proteasome or serine protease activities results in elevated levels of modified and misfolded proteins, leading to the chronic activation of a heat shock response. For example, exposure of eukaryotic cells to the proteasome inhibitors, MG132 and lactacystin, activate both HSF1 and HSF2. Likewise, the serine protease inhibitors DCIC, TPCK, and TLCK also induce these factors and elevate transcription of Hsp genes.

The aberrant expression of Hsps observed in many cancers has led to various hypotheses that the chronic upregulation of chaperones could afford the cancer cell with the capacity to suppress multiple independent mutations that affect protein function. Equally compelling are arguments that the transient activation of the heat shock response and elevated levels of chaperones establish a cytoprotective state that is resistant to cell death signals and with the capacity to endure stressful conditions. For these reasons, there has been much interest in the therapeutics of the heat shock response and chaperones. The discovery that inhibitors of Hsp90 function could block cell proliferative pathways important in cancer has led to the development of a family of structurally related benzoquinone ansamycins including geldanamycin and its less toxic derivative

17-AAG and the fungal antibiotic radicicol. Although structurally distinct, radicicol and geldanamycin both bind to the ATP binding domain of Hsp90 and inactivate Hsp90 function, resulting in decreased activity and levels of essential key signal transduction proteins including steroid receptors, cell cycle kinases, transcription factors, and p53, with immediate consequences on cell proliferation. Indeed, a recent report suggested that Hsp90 in tumor cells may have selectively greater affinity for 17-AAG, associated with presence of Hsp90 in such cells in multichaperone complexes as opposed to a predominantly noncomplexed state in normal cells. Regardless, a consequence of treatment with these Hsp90 inhibitors is that they produce constitutive activation of the heat shock response, presumably by derepression of HSF1.

A speculation and systems considerations

It is intriguing to consider that among the Hsp90 targets are the hormone regulated intracellular receptors that share many features in common with the regulation of the heat shock response. Both provide inducible responses regulated at the level of transcriptional control, and involve families of transcription factors that cycle between inert and activated states by adopting multiple conformations and rapid reversible kinetics of activation. Chaperone networks are employed in both systems to maintain the activators in an inert but responsive state, and later in the regulatory cycle, to repress and disassemble the activated factor. Perhaps transcription factors such as hormone receptors and HSF1, and other signaling molecules including kinases and caspases, have complex folding requirements that

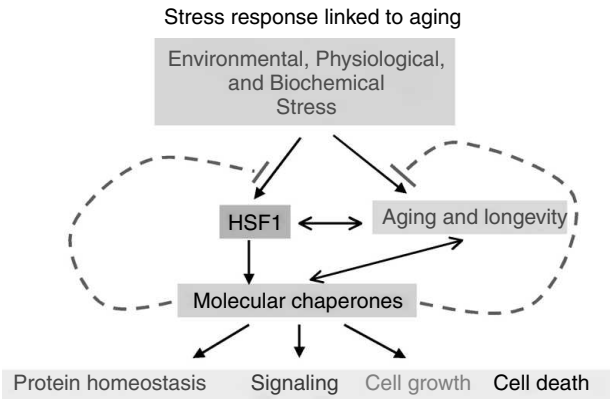

Fig. 6 Diverse roles of HSF1 and the heat shock response, including an effect on aging observed in *C. elegans*. In the presence of proteotoxic stress inducers, HSF1 is activated, leading to the elevated expression of molecular chaperones and other proteins that regulate protein homeostasis. These events influence stress signaling pathways, cell growth, and cell death. Recent results also indicate that HSF1 and certain molecular chaperones influence aging. See for example, the report of Hsu et al, 2003, where increased HSF-1 activity extended *C. elegans* lifespan and reduced HSF-1 activity shortened it. Such effects were linked to the DAF-16 insulin/IGF1 pathway and to small heat shock protein expression.

may have arisen from exon shuffling and other evolutionary pressures, for which chaperones have become essential to regulate alternate conformational states. Or did this arise because of the unique properties of chaperones and cochaperones to generate stable folded intermediates that have become prime targets in the design of regulatory complexes?

From a systems perspective, the linkage of signaling pathways that feed back through a shared pool of chaperones posits the presence of hierarchical genetic networks through which changes in the cellular environment can be transduced (Fig. 6). In support of this speculation, aberrant expression of individual chaperones or cochaperones influences proliferation and development by preventing or enhancing cell growth and cell death. For example, decreasing the levels of Hsp90, whether by mutation or by the Hsp90 inhibitor geldanamycin, uncovers a Pandora's box of developmental abnormalities in Drosophila and Arabidopsis. Likewise, heat shock and elevated levels of Hsp70 have growth inhibitory effects on signaling pathways.

3 Unfolded Protein Response (UPR) of the Eukaryotic Endoplasmic Reticulum

A further stress response system has been recognized in the secretory endoplasmic reticulum of eukaryotes, signaling the presence of unfolded proteins and producing transcriptional and translational responses. In some respects the UPR parallels the σ^E-mediated stress response of the bacterial periplasm, an analogous secretory compartment, where, likewise, signals must transmit across a membrane to reach the site of chromosomal transcription. The eukaryotic UPR induces the transcription of several hundred genes whose products increase both the folding capacity of the ER and also its ability to rid itself of misfolded proteins by retrotranslocation to the cytosol followed by proteasomal degradation. A further arm of the UPR, however, involves attenuation of general protein translation, which decreases the ''load'' of unfolded proteins arriving in the ER.

The UPR system is regulated by three ER transmembrane proteins, IRE1, ATF6, and PERK (Fig. 7a). These components appear to bind the Hsp70 chaperone protein in the ER, known as BiP, under normal conditions, but in the setting of unfolded proteins, BiP is recruited to these substrates, freeing these transmembrane components.

The first signaling mechanism to be understood is that mediated by IRE1, articulated from elegant experiments in a yeast system by Peter Walter and his colleagues in the mid-1990s. IRE1 responds to accumulation of unfolded proteins by homodimerization and activation of both a kinase activity and a site-specific endonuclease activity contained in a domain on the cytosolic side of the ER membrane, which enables splicing and efficient translation of the message for a transcriptional activator (HAC1 in yeast; Xbp1 in mammals; Fig. 7a). This activator binds and activates specific upstream sequence elements in many UPR-inducible genes. ATF6 (activating transcription factor 6) can also bind regulatory elements. This component is synthesized as a larger ER transmembrane precursor protein that is retained in the ER until unfolded proteins trigger its translocation to the Golgi, where it is cleaved in its transmembrane region by

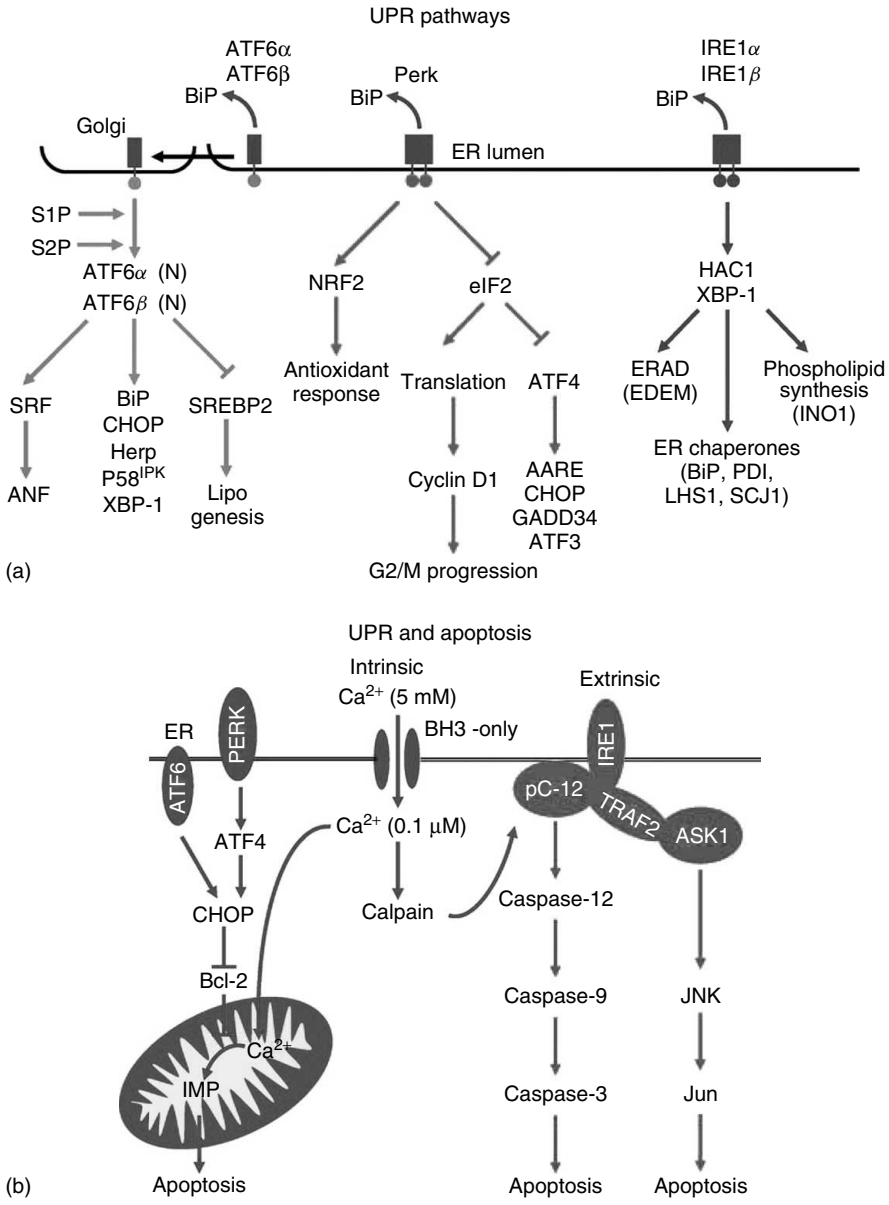

Fig. 7 Pathways of the unfolded protein response (UPR) by which the eukaryotic endoplasmic reticulum recognizes accumulation of unfolded proteins and signals to the nucleus and cytosol. (a) IRE1 and ATF6 trigger induction of transcription of components that enhance the folding and secretory capacity of the ER, while PERK inhibits general translation in the cytosol, diminishing the load of unfolded protein reaching the ER. (b) Prolonged activation of the UPR can lead to apoptotic cell death via the same proximal pathways, involving IRE1, ATF6, and PERK, but with distal components such as ATF4, CHOP, and JNK activating apoptosis. Figure taken from Schröder, M., Kaufman, R.J. (2005) ER stress and the unfolded protein response, *Mutat. Res.* **569**, 29–63.

two proteases known as S1P and S2P, which are also involved in the processing of the sterol response factor SREBP. Cleavage releases a cytosolic fragment of ATF6 that enters the nucleus and binds to ER stress response DNA elements including that for the IRE1 splicing target, Xbp1. Thus, ATF6 and IRE1 cooperate to activate the stress response. In a third arm of the UPR, the transmembrane kinase, PERK, first identified by David Ron and his colleagues, becomes activated, phosphorylating eIF2α and attenuating general translation, while at the same time enhancing translation of UPR-induced messages.

At the effector level, the UPR induces a host of components. Included are ER lumenal components involved in protein folding, such as the chaperones BiP (an Hsp70) and the DnaJ protein SCJ1, but also induced are components involved in disulfide bond formation, such as Ero1 and PDI (protein disulfide isomerase). Also induced are a host of glycosylation enzymes. At the level of the ER membrane, components of the translocon as well as signal peptidase are induced, and also induced is the class of components involved with ERAD (ER-associated degradation), including derlin, a putative protein retrotranslocase; Ubc7, a ubiquitinating component, and several components of the proteasome pathway. Additionally induced are components of vesicle trafficking and of lipid metabolism, reflecting a general induction of secretory functions by the UPR.

Notably, prolonged UPR activation can lead to apoptotic cell death, involving several pathways (Fig. 7b). One involves IRE and a Jun inhibitory kinase, and another involves ATF6 and activation of the bZIP transcription factor CHOP.

The UPR is implicated in a range of normal physiological states such as B cell maturation, where the ER must massively expand its capacity to import, fold, assemble, and export antibodies. More generally, the UPR appears to balance the translational burden relative to the maturational capacity of the ER. This may reflect the cell's overall metabolic state. Thus, as has been suggested, the UPR may play a contributing role in disease states. For example, obese mice were shown to exhibit increased levels of PERK and eIF2α phosphorylation, as well as elevation of the ER stress-responsive protein GRP78, in liver and fat. This ER stress-responsive state was associated with diminished insulin receptor signaling, most immediately mediated by Jun kinase-dependent phosphorylation of IRS-1 (insulin receptor substrate-1). This was likewise observed *in vivo*, in Xbp-1 +/− mice, lacking compensatory capacity for ER stress – these mice developed peripheral insulin resistance and type II diabetes. Consistently, and independently, mutations in PERK also lead to diabetes in mice and man. Thus, a link between chronic ER stress and peripheral insulin resistance seems to be indicated. The nature of how obesity translates into ER stress remains unclear, but it seems inescapable that stress response is integrated with metabolic regulation in the ER.

4
Chaperone Effectors of the Heat Shock Response

4.1
Chaperonin (Hsp60) System

A major sigma32-responsive heat shock operon in bacteria is that encoding the double ring chaperonin, GroEL, and its cooperating single ring lid structure,

GroES. These two ring structures mediate ATP-dependent polypeptide chain folding, with nonnative protein binding to the hydrophobic wall of the central cavity of an open GroEL ring via exposed hydrophobic surfaces, followed by folding to the native state occurring inside the encapsulated and hydrophilic chamber formed upon binding of the GroES lid and ATP to the same GroEL ring. Chaperonins resembling GroEL/GroES are also found in mitochondria (Hsp60/Hsp10) and chloroplasts (Rubisco binding protein/cpn10). A second family of chaperonins, functioning with a built-in lid structure, is found in archaebacteria (thermosome) and in the eukaryotic cytosol (CCT or TRiC). In all of these contexts, the chaperonins are essential for cell growth, indicating that the kinetic assistance they provide to polypeptide chain folding is essential under all conditions.

More explicitly, the role of these assemblies, like other chaperones, is to prevent or reverse off-pathway steps of folding that can occur under *in vivo* conditions. While Anfinsen and his coworkers showed in the late 1950s that the primary amino acid sequence of a polypeptide chain contains all of the information required to direct folding to the native state typically lying at the energetic minimum, under conditions in the cell, including high temperature and high solute concentration, polypeptide chains, particularly ones larger than 150 amino acids and with multiple domains, often cannot efficiently reach their native state. Under such conditions, in seeking to reach the energetic minimum, they face a more rugged folding ''landscape,'' with the possibility of landing in local energetic minima, kinetically trapped states. In structural terms, such states, usually misfolded but in some cases on-pathway intermediates, expose hydrophobic surfaces that will become buried in the native state. These can recruit one molecule to another, leading to irreversible multimolecular aggregation, a functional dead end for the proteins involved, and a state that can be damaging to cells, as for example, in the case of the amyloid diseases. The action of molecular chaperones in general is to bind such states incipiently, via the exposed hydrophobic surfaces, masking such surfaces and preventing aggregation. Chaperones then release the bound protein, often through the action of binding of ATP, allowing the substrate to attempt to pursue a correct pathway of folding or biogenesis. The chaperonin class of molecular chaperones acts uniquely to support folding to native form by releasing bound proteins into an encapsulated hydrophilic cavity, enforcing folding in isolation where aggregation cannot occur. The hydrophilic environment likely contributes to productive folding as it energetically favors burial of hydrophobic surfaces to the interior of the folding protein and exposure of hydrophilic surfaces to the outside, properties of the native state.

History and physiology GroEL was originally uncovered in the early 1970s by Georgopoulos and coworkers and independently by investigators in Japan as a host gene required for phage assembly. Cells bearing mutations in this operon could survive infection with λ or T4 phage, and when lysates were examined by EM, they contained aggregated head or tail structures. GroEL mutant cells, in the absence of phage infection, were also observed to be defective in growth, particularly at high temperature. A role in macromolecular assembly was originally suggested, supported by experiments by Ellis and coworkers in 1980 with a chloroplast homolog that suggested a role for it in

assembly of the abundant hexadecameric CO_2-fixing enzyme Rubisco. Ultimately, however, a role in monomeric polypeptide chain folding was elucidated by studies of an yeast mutant affecting an additional homolog in mitochondria, Hsp60, which was observed to be required for the folding of imported proteins that pass through the mitochondrial membranes as unfolded monomers. A role of these double ring ''chaperonins'' in polypeptide chain folding was confirmed by reconstitution experiments, first with isolated mitochondria, then *in vitro* with the purified bacterial chaperonin, GroEL and its cochaperonin GroES, demonstrating assisted folding of imported or chemically denatured polypeptides, respectively, in the presence of ATP.

GroEL–GroES-mediated protein folding *in vitro* was first accomplished by Lorimer and coworkers as a two-step reaction. In the first step, a nonnative protein unfolded in denaturant was diluted into a buffer containing the GroEL double ring, and formed a stoichiometric complex with it. Such a binary complex formation protected the substrate protein from complete and irreversible aggregation that supervened in the absence of chaperonin. Later EM studies showed that in such complexes the bound substrate protein localizes inside the central cavity of a chaperonin ring. In the second step, upon addition of ATP and the GroES single ring cochaperonin, production of the native state of the bound protein occurred, associated with its release from GroEL, over a period of several minutes. The mechanism of GroEL/GroES-mediated folding is further detailed below.

The second family of chaperonins was identified via studies of a temperature-induced protein in thermophilic archaebacteria that had the same size as the subunit of the Hsp60 family under both native and denaturing conditions. When its primary sequence was determined, it was found to be homologous to an essential protein of the eukaryotic cytosol called TCP1. Cold-sensitive conditional mutation of tcp1 in yeast led to impaired tubulin biogenesis, but the role of this protein had remained unclear. This protein was recognized to be a subunit of the TCP1 or CCT (chaperonin containing TCP1) complex. This complex, composed of 8 related but nonidentical subunits per ring, was found to play an essential role in mediating folding of actin and tubulin but also, more recently, of G_α transducin and β-propeller proteins.

The chaperonins are abundant, reflecting their involvement in assisting the folding of many proteins. In bacteria, for example, their abundance amounts to ~1% of soluble protein under normal conditions, and they mainly provide assistance to folding of newly translated polypeptides. A number of studies estimate that ~10 to 20% of newly made species are assisted by this system in reaching the native state. Under stress conditions such as heat shock, however, the synthesis of the bacterial components rises to a level of 10 to 15% or more of total soluble protein, an amount of these ring complexes equivalent to or greater than the number of ribosomes. Under these conditions, the chaperonin system acts particularly to protect preexistent proteins from irreversible misfolding and aggregation, and there may be a large percentage of proteins requiring such action.

In mitochondria, a significant fraction of the imported polypeptides, approximating 50% from a proteomic study, require the action of Hsp60 and its cooperating component Hsp10 in order to be properly folded. In the eukaryotic cytosol, the CCT chaperonin is approximately a tenth

as abundant as GroEL is in bacteria, but it is essential, as mentioned, to mediating folding of actin, tubulin, transducin, β-propeller proteins, and likely others as well. The range of substrate proteins recognized by CCT remains to be fully resolved. In archaebacteria, by contrast, the thermosome has a high basal abundance, and under heat shock conditions it becomes induced as virtually the only protein synthesized. The lack of facile genetic manipulation in the archaeal system has made difficult a full evaluation of substrates and action. It is notable that both CCT and the thermosome employ another chaperone known as *prefoldin*, a jellyfish-shaped component that binds nonnative proteins via hydrophobic tentacle tips, as an agent that delivers substrate proteins to them. In the bacterial cytoplasm, it appears that nascent chain chaperones such as trigger factor, which binds nascent chains at the ribosome, and DnaK, may interact with substrates occupying more extended conformations, before they arrive at the chaperonins in collapsed globular states.

Chaperonin architecture

GroEL The bacterial chaperonin assembly is composed of identical 58-kDa subunits arranged in two back-to-back seven-membered rings (Fig. 8). Each subunit is folded into three domains, an equatorial domain housing a nucleotide pocket, the collective of which form the waistline of the cylinder; an apical domain at the terminal end of the cylinder, the collective of which form a hydrophobic polypeptide binding surface at the cavity-facing aspect of a ring; and a hingelike intermediate domain between the equatorial and apical domains, which enables nucleotide-directed opening of the apical domains. The equatorial domains form tight contacts of the subunits with each other, both around a ring and between rings, providing a stable base from which movements of the intermediate and apical domains are directed by nucleotide and GroES binding. ATP is bound and hydrolyzed cooperatively within a ring but anti-cooperatively between them. As indicated, the apical domains positioned at the terminal ends of the GroEL cylinder present a hydrophobic surface at their cavity-facing aspect that is involved with binding nonnative polypeptides in the central cavity (see Fig. 8 rightmost panels, yellow). Such binding involves hydrophobic contacts between the apical cavity lining of the chaperonin and hydrophobic surfaces exposed specifically in nonnative polypeptides, surfaces that will be buried to the interior in the native state. It is such exposed hydrophobic surfaces in substrate proteins, as mentioned above, that are responsible for the

Fig. 8 Chaperonin structures. Crystallographic models of the bacterial chaperonin, GroEL (top row; pdb 1GRL), GroES (middle row), and GroEL–GroES complex (pdb 1AON) are shown, as ribbons traces (left panels) and space filling (right-hand panels), illustrating the arrangement of subunits (middle columns) and domains (left column). a, apical; i, intermediate; e, equatorial domains. Note that association of GroES with a GroEL ring leads to large-scale elevation and twisting of its apical domains (compare top and bottom rows). This is attended by a change of cavity wall character from hydrophobic (yellow in right panels) to hydrophilic (blue in top GroES-bound ring of lower right panel). Productive folding proceeds inside of the GroES-encapsulated cis ring, whereas the initial binding of nonnative polypeptide occurs to an open ring of an asymmetric GroEL–GroES–ADP complex. (See color plate p. xliii.)

undesirable behavior of multimolecular aggregation, which is associated with loss of substrate function, and with the harmful effects to the cell of protein aggregation. Thus, binding by the chaperonin, mediated through multiple surrounding apical domains simultaneously, effectively forestalls multimolecular aggregation. Upon binding ATP and then GroES to a GroEL ring, this same hydrophobic surface is elevated and twisted away from its original position, effectively removed from facing the central cavity, to form new contacts with the cochaperonin GroES through hydrophobic segments in each of its mobile loops. Such movement away from bound substrate polypeptide serves to release the polypeptide into what is now a hydrophilic chamber in which it can productively fold (Fig. 8, lower right panel, top ring).

GroES This single ring structure is composed of seven identical subunits, each comprised of a β-barrel from which extends a mobile loop segment of 17 to 18 amino acids that is freely mobile in the stand-alone state but which become immobilized in GroEL-GroES complexes (Fig. 8 middle and lower rows). Each GroES mobile loop contacts a hydrophobic aspect of a corresponding GroEL apical domain via a hydrophobic edge containing the sequence IVL. The inside aspect of the GroES cavity itself in GroEL–GroES complexes forms a smooth continuation of the GroEL cavity (Fig. 8).

Action in assisting protein folding The action of chaperonins in assisting folding is provided at two different steps of the reaction cycle (Fig. 9). During the step of binding nonnative protein in an open ring (left panel), the off-pathway events of misfolding and aggregation are prevented. Such binding may act, as discussed below, to effectively unfold nonnative proteins, giving them a fresh trial at productive folding at each round of binding to the chaperonin, occurring upon subsequent ATP/GroES-driven release into the chaperonin cavity (panel 2). During the step of such release, productive folding is supported by encapsulation in solitary confinement, by

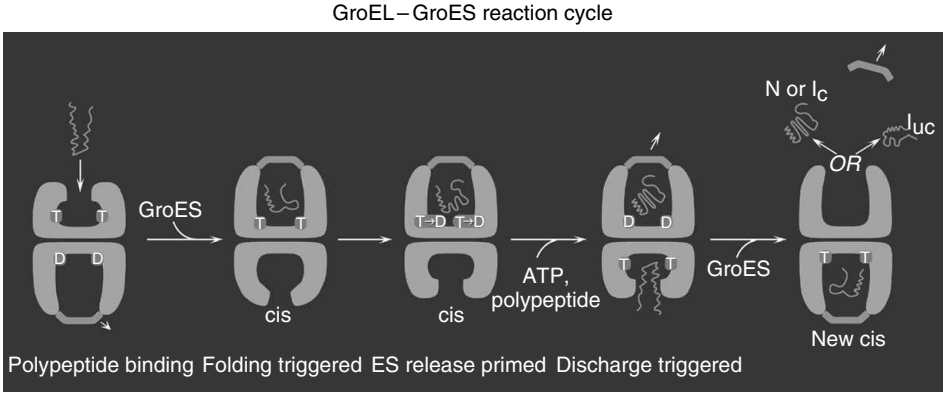

Fig. 9 GroEL–GroES–ATP-mediated folding cycle. Polypeptide is designated as a yellow line, GroES is designated in orange. T, ATP; D, ADP. I_c, intermediate folded form committed to reaching the native state in the bulk solution, that is, a state for which GroEL has no affinity. I_{uc}, nonnative form that is uncommitted, that is, that will rebind to a GroEL ring. See text for discussion of the steps of the reaction cycle. (See color plate p. xxvi.)

hydrophilic wall character and also by the narrow confinement of the walls, which may limit the off-pathway states that can be populated, excluding, for example, extended states.

An action of unfolding nonnative proteins in association with binding them in an open chaperonin ring has been supported by findings that chaperonin-bound nonnative proteins are very susceptible to proteases and also very susceptible to hydrogen-deuterium exchange, indicating little or no stable structure. Such a relatively unfolded state could be reached by two general mechanisms. One, called *thermodynamic partitioning*, recognizes that there is an ensemble of unfolded states for any given polypeptide species in the bulk solution and postulates that the chaperonin has greater affinity for the less folded of these states. Binding them will thus shift the equilibrium of states by mass action toward the less folded, effectively acting as an unfolding action. The second mechanism of unfolding would involve catalyzed unfolding, in which a polypeptide coming in contact with the chaperonin cavity wall becomes bound by multiple surrounding apical domains, which could act to unfold a protein. In one experiment, a catalytic effect of the chaperonin GroEL, supplied in substoichiometric amounts, on a small RNAse has been observed by hydrogen-deuterium exchange. Thus, either or both of these mechanisms could effectively reverse misfolding in the act of binding to chaperonin.

The nucleotide cycle The chaperonin reaction cycle is illustrated in Fig. 9. The two rings of GroEL behave in an asymmetric manner as a function of the behavior of ATP binding and hydrolysis, occurring cooperatively in the seven subunits of a ring but anti-cooperatively between rings. As a consequence of this, since GroES binding to a ring requires occupancy of the ring with ATP, which produces a degree of apical domain elevation and twist that enables initial interaction, GroES, like ATP, is asymmetrically bound to GroEL. The normal acceptor state for a nonnative polypeptide is thus the open ring of a GroEL–GroES–ADP asymmetric complex (panel 1). Polypeptide entering the open ring associates through its own exposed hydrophobic surface with the surrounding hydrophobic apical domains. The arrival of ATP at the same ring as polypeptide is an allosteric trigger to release the ligands from the opposite ring, a step that is accelerated by the coincident binding of nonnative polypeptide. In the presence of bound ATP, the polypeptide-bound GroEL ring binds GroES, and the further large apical domain movements attendant to this step effectively remove the hydrophobic binding surface from the central cavity, and trigger ejection of nonnative polypeptide off the cavity wall and into the now hydrophilic folding chamber (Fig. 9, panel 2). This folding-active state is the longest step of the GroEL–GroES reaction, ~8–10 s, following which ATP hydrolysis in the GroES-bound (cis) ring weakens the affinity of GroEL for GroES, "priming" the release of GroES (panel 3), which is triggered by the allosteric signal subsequently produced by ATP arriving in the opposite ring (panel 4). All of the cis ligands are ejected (panel 5): GroES, polypeptide whether it is native or not, and ADP. In the case of polypeptide, only a fraction of the molecules reach native form in any given cycle. For example, only ~5% of cis ternary complexes containing the monomeric enzyme, rhodanese, produce the native enzyme in a single round, so many additional cycles of apparently all-or-none folding are required in order for all of the molecules

to reach native form. Nonnative proteins released into the bulk solution have been shown to be unable to attain the native state in that location in an experiment preventing their rebinding to GroEL. Thus, in the cell, they must be rebound either by GroEL or by other chaperones, attempting once again to reach native form. Alternatively, if unable to be correctly folded, they are likely to be recognized and degraded by the proteolytic machinery.

Behavior during heat shock Early studies of GroEL/GroES showed that the abundance of these components was increased by more than 10-fold during heat shock, with levels accreting to 10 to 15% of total soluble protein. This is the result of an elevation of synthesis of these components directed via σ^{32} and the promoter element in the *GroESL* operon, as discussed earlier. Additional studies done later *in vitro* indicate that the chaperonins themselves are stable up to 60 °C, and the ATPase activity of GroEL is likewise accelerated. Yet under these conditions, efficiency of refolding is reduced, potentially because newly folded proteins become rapidly unfolded. Following relief of thermal exposure, however, productive folding promptly resumes.

4.2 Hsp70 System

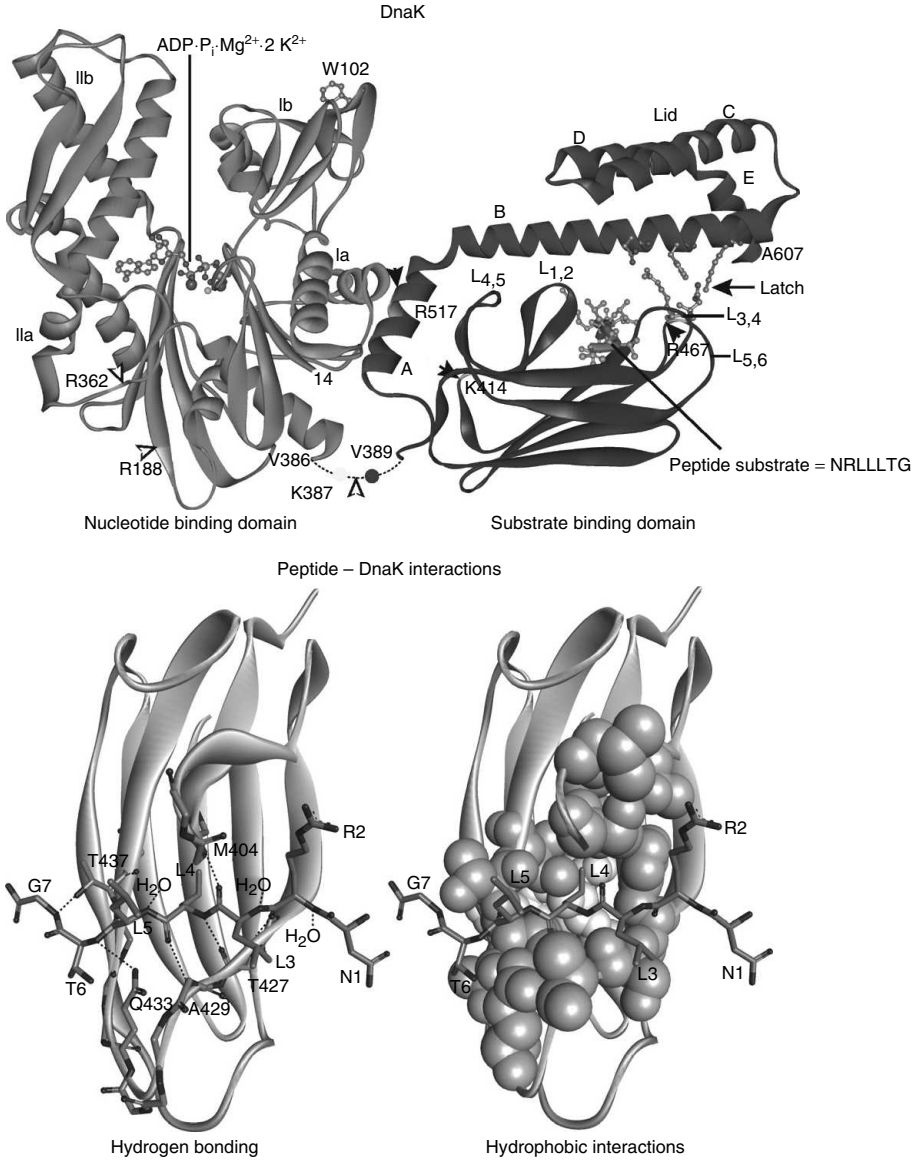
Another bacterial operon under the control of σ^{32} is that encoding the chaperones DnaK (Hsp70) and DnaJ. These two proteins function together in the bacterial cytoplasm and in most other cellular compartments as an ATP-dependent chaperone machine. Unlike the GroEL/ES ring structures that bind nonnative polypeptide multivalently in a ring and carry out refolding in an encapsulated space, these components act as monomers, binding short hydrophobic stretches of amino acids present in extended segments of polypeptide chain, then releasing the chain into the bulk solution for further biogenesis.

These widely distributed chaperones have diversified through evolution in structure, localization, and function; and individual Hsp70s generally function with specific J-proteins. Bacteria have three or more related Hsp70s in their cytosol, but the major one, with general action, is DnaK. It makes up 1% of bacterial protein under optimal growth conditions and rises to 3% under stress conditions. In eukaryotes, there are multiple Hsp70s and J-proteins, localizing both in the cytosol and in major organelles, including

Fig. 10 Structure of the bacterial hsp70 protein, DnaK. Models of the crystal structures of the two major domains, the nucleotide binding domain (left, in green, pdb 1BUP) with complexed nucleotide, and the substrate binding domain with a complexed heptapeptide (right, in blue, pdb 1DKX). The two domains are joined together by a dotted line that signifies a linker region between the two domains. The structure and position of this linker and the orientation of the two domains relative to each other remain unknown. The peptide binding site is formed by loops emanating from a β-sheet, and an overlying α-helical lid structure contributes to opening and closing of access to the site. Lower panel shows the contacts formed between the heptapeptide and the binding site from a vantage point of the helical lid. Both hydrogen bonds (left, dashed lines) and hydrophobic interactions (right, DnaK side chains in space filling and those of the peptide as stick representation) contribute to binding of the central hydrophobic portion of the heptapeptide (Figure panels taken from Mayer, M.P., Bukau, B. (2004) Regulation of Hsp70 Chaperones by Co-chaperones, in: Buchner, J., Kiefhaber, T. (Eds.) *Protein Folding Handbook*, Part II, Chap. 15, Wiley-VCH, Weinheim, pp. 508–548). (See color plate p. xxxviii.)

the nucleus, endoplasmic reticulum, mitochondrion, and chloroplast.

While these different machines have diverged in structure and function, a fundamental mechanism of action is shared. The Hsp70s bind short extended hydrophobic stretches of polypeptide through a hydrophobic archway in the 15-kDa COOH-terminal β-sandwich domain (Fig. 10, top right), an interaction regulated by the binding and hydrolysis of ATP in the cleft of the bilobed N-terminal domain (Fig. 10, top left). Substrate protein can be directly bound by Hsp70 in



its ATP-bound state, but in many cases it seems likely that substrate is "delivered" to an Hsp70 peptide binding site by a J-protein partner chaperone that forms the initial interaction with substrate via its own C-terminal binding site for hydrophobic amino acid sequences (Figs. 11, 12c). Subsequent hydrolysis of ATP by the Hsp70 is strongly stimulated by interaction with the J-protein, an interaction remote from the peptide binding sites between the so-called "J domain" of the partner J-protein and the nucleotide binding domain of the Hsp70 protein (Figs. 10, 11, 12b). ATP hydrolysis leads to an allosterically directed large increase in affinity of the Hsp70 for its substrate protein, characteristic of the ADP-bound state of Hsp70s. The substrate thus becomes tightly bound in the Hsp70 peptide binding pocket until a nucleotide

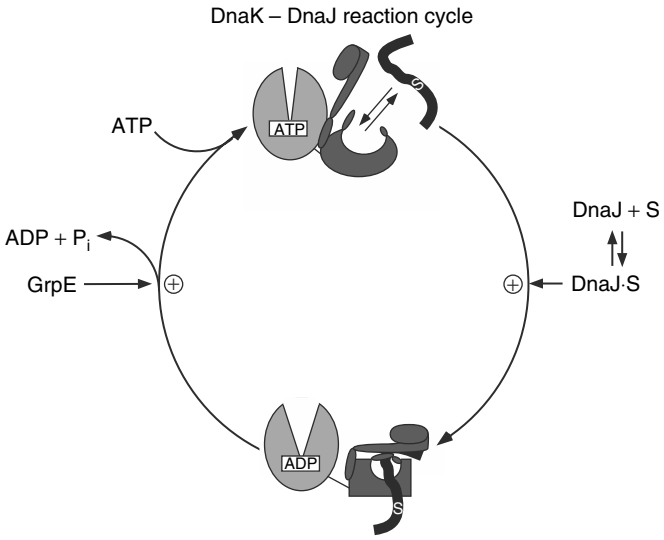


Fig. 11 DnaK–DnaJ reaction cycle. DnaK is represented schematically, with nucleotide binding domain colored light gray and peptide binding domain a darker gray. Nonnative substrate protein, S, is shown in black. The ability of DnaK to interact with substrates in its ATP-bound form is shown at the top, with rapid on and off-rates signified by the arrows. DnaJ's ability to also recognize substrate and to deliver substrate to DnaK is shown at the right. Such delivery of substrate by DnaJ, associated with binding to DnaK, is accompanied by accelerated ATP hydrolysis by DnaK (see text), associated with a locking in of bound substrate protein by the ADP-bound state of DnaK. In bacterial and mitochondrial systems, a nucleotide exchange factor, GrpE, binds to the ADP-bound nucleotide pocket of DnaK (mhsp70) (see Fig.13), releasing the nucleotide and allowing entry of ATP. In other hsp70 systems, such an exchanger is not operative, but other factors that modify nucleotide binding or residence can be involved (see Mayer, M.P., Bukau, B. (2004) Regulation of Hsp70 Chaperones by Co-chaperones, in: Buchner, J., Kiefhaber, T. (Eds.) *Protein Folding Handbook*, Part II, Chap. 15, Wiley-VCH, Weinheim, pp. 508–548; figure modified from their review).

Hydrophobic depression comprising the substrate binding site is designated in yellow. This assignment has been supported by mutational studies. Panels B and C taken from Mayer, M.P., Bukau, B. (2004) Regulation of Hsp70 Chaperones by Co-chaperones, in: Buchner, J., Kiefhaber, T. (Eds.) *Protein Folding Handbook*, Part II, Chap. 15, Wiley-VCH, Weinheim, pp. 508–548. (See color plate p. xl.)

exchange event opens the cleft by replacing bound ADP with ATP, associated with reduced affinity for substrate and its dissociation, freeing it for subsequent steps of folding or targeting (Fig. 11). Nucleotide exchange in some cases is catalyzed by an exchange factor, for example, the protein in the bacterial cytoplasm known as *GrpE*.

Using the foregoing general mechanism, Hsp70 proteins carry out a variety of functions in the cell, including the following:

1. Assisting in the folding of newly translated proteins emerging from or recently departed from the ribosome. In the former case, binding to nascent

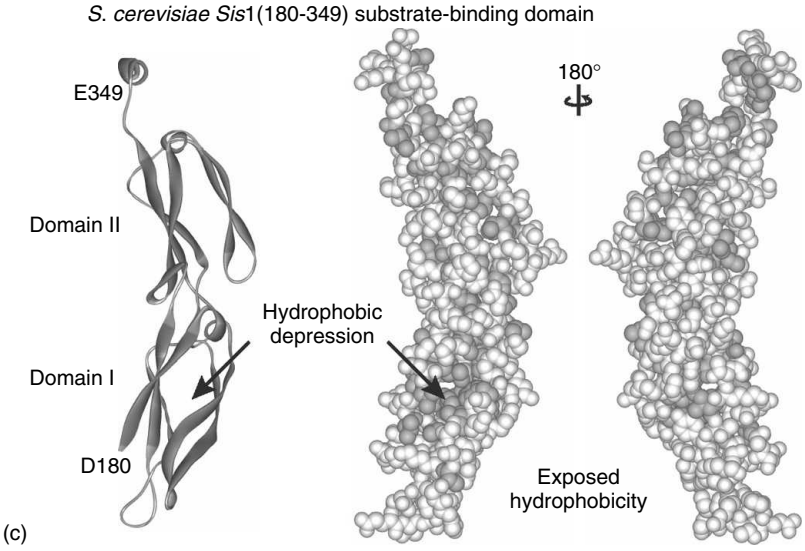

Fig. 12 (*Continued*)

chains may serve to prevent premature folding of a polypeptide. For example, where there are interactions in the native state between N and C-terminal regions, such a ''holding'' action of the N-terminal region could prevent premature folding until the C terminus has been translated and is available. In the case of proteins already released from the ribosome, binding by Hsp70 may prevent misfolding and aggregation during trials at correct folding to the native state.

2. Assisting posttranslational protein translocation across membranes, for example, translocation into the ER or mitochondria. On the cytosolic (cis) side of such membranes, Hsp70s act to maintain polypeptides in ''loose'' conformations, allowing them to engage and pass through translocons. Inside the organelles, at the trans side of membranes, Hsp70s act to facilitate translocation by binding unfolded stretches of polypeptide, biasing their progressive forward movement through the translocon and in some cases potentially providing a forceful pulling action.
3. Reversing incipient aggregation, under normal conditions or under stress conditions. Here Hsp70s appear to be able to pry apart low order aggregates of two to three monomers, potentially by shifting an equilibrium between such states toward that of bound monomer. An action on higher-order aggregates can also be mediated, but here the action of specialized Hsp100 hexameric AAA+ ring assemblies such as Hsp104 or ClpB, discussed in the following sections, is required. Recently it has been demonstrated that such disaggregating action by ClpB involves passage of monomers through its central channel, assisted by the action of Hsp70.
4. Mediating dissociation of specific oligomeric proteins. In bacterial cells, for example, such dissociation is

observed in the λ phage biogenesis system, involving dissociation of λP from λO-λP-DnaB ternary complexes, mediated by the Hsp70 system. In eukaryotic cells, an example is the dissociation of clathrin triskelions during clathrin coat disassembly, with Hsc70 recruited by the DnaJ domain of a clathrin-associating component, auxilin. Recent cryoEM studies of clathrin and clathrin–auxilin complexes suggest that Hsp70 may bind to a hydrophobic unstructured C-terminal region of the clathrin heavy chain subunit that localizes inside the clathrin lattice.

5. Facilitating biogenesis of steroid receptors and signal transducing kinases in the eukaryotic cytosol by participation in biogenesis of Hsp90 complexes. Here, cytosolic Hsp70 proteins function in cooperation with J-proteins to mediate an early step in the biogenesis of these molecules on their pathway of assembly into Hsp90 multichaperone complexes.
6. Regulating the heat shock response via binding of the bacterial heat shock regulatory transcription factor, σ^{32}, as discussed above, sequestering it from binding to RNAP. A similar action appears to occur in eukaryotes, with Hsc70 binding to the heat shock factor HSF.

History and general physiology Like GroEL/GroES, DnaK and DnaJ were first identified in the 1970s as genes required for growth of phage-λ. While GroEL/GroES are necessary for phage head and tail morphogenesis, DnaK and DnaJ are critical for the replication of λ DNA. DnaK/J were found to be important for remodeling the protein complex required for initiation of λ DNA replication, mediating an action of dissociation of a component from a ternary complex. During these studies, an Hsp70 of the lumen of the endoplasmic reticulum, BiP, was observed to complex with immunoglobulin light chains in the absence of partner heavy chains, a clue that led to appreciation of the involvement of Hsp70 proteins in protein biogenesis. However, a role in binding monomeric polypeptide chains was not clear until *in vivo* experiments with yeast reported in 1988 by a collaboration of Craig and Schekman groups, and *in vitro* ones reported by Blobel and coworkers, demonstrated that lack of Hsp70s had deleterious effects on protein conformation, preventing precursor proteins in the cytosol from occupying ''loose'' conformations required for entering either the ER or mitochondria. Similarly, a blocking of the function of Hsp70s at the other side of these membranes inside the respective organelles led to a blocking of translocation into them, as observed by the combined work of the groups of Craig and Pfanner/Neupert, suggesting that the role of binding the entering extended chains is required for translocation. Later experiments *in vitro* corroborated an action of Hsp70 on monomeric polypeptides, showing that purified DnaK, DnaJ, and GrpE were able to facilitate the refolding of denatured firefly luciferase. Recent experiments indicate that DnaK interacts with up to 18% of newly synthesized proteins prior to their folding, and that the action of the DnaK machinery is essential for survival upon exposure to stress such as heat shock.

Structure of Hsp70s, DnaJ proteins, and GrpE

Hsp70 Hsp70s are highly conserved monomeric proteins of approximately

70-kDa molecular mass. An amino terminal 44-kDa adenine nucleotide binding domain has a low intrinsic ATPase activity (Fig. 10). The carboxy terminus contains two regions. The more amino-terminal subdomain is the substrate binding region consisting of eight antiparallel β-strands that form a hydrophobic cleft that, in both peptide binding experiments and in a cocrystal, interacted with five consecutive hydrophobic residues in a bound peptide. Binding was favored by the presence of basic residues flanking the hydrophobic stretch in the substrate peptides. A survey by Bukau and coworkers of a number of proteins suggested the presence of a recognizable hydrophobic stretch that was on average every 36 amino acids across primary structures. Where correspondent three-dimensional native structures were available, in many cases these regions localized to a buried hydrophobic core of the native state.

Concerning the mechanism of Hsp70 binding, an α-helical region in the substrate binding domain of DnaK, following the sequences forming the β-sheet sandwich of the peptide binding cleft, appears to be able to form a lid over the bound peptide (Fig. 10). Deletion of this region affects affinity for nonnative substrates. The function of the C-terminal-most 10-kDa segment of Hsp70s, the most divergent region among the family, is less well understood, but it may play a role in modulating the interaction between the ATPase and substrate binding domains, or it may mediate interaction with partner J-proteins.

The two nucleotide states of Hsp70 have profoundly different characteristics in binding polypeptide substrates. In the ATP-bound state, the affinity for substrate is very low, with the on-rates and off-rates being very rapid (on the order of milliseconds) (Fig. 11). Interaction with substrate in the ADP-bound state, by contrast, is quite stable, with the off-rates and on-rates both being relatively slow (on the order of minutes) (Fig. 11). It is thought that allosterically mediated conformational changes of the COOH-terminal peptide binding domain are brought about by nucleotide binding in the NH_2-terminal domain. Such binding affects, for example, positioning of the α-helical lid, affecting affinity for nonnative proteins. In the ATP-bound state, the lid is disengaged allowing rapid entry and exit of substrate protein; in the ADP-bound state, the lid is proposed to be clamped tightly over the peptide binding pocket preventing release.

J-proteins J-proteins as a class are a very divergent group of proteins, having in common a J-domain that interacts with the ATPase domain of Hsp70 (Fig. 12a,b). J-domains are composed of four α-helices and have a highly conserved histidine, proline, aspartic acid (HPD) tripeptide found to be critical for J-domain function. While all J-proteins interact via HPD segments with Hsp70 ATPase domains, this alone is not sufficient to determine the partnering relationship, and other regions of J-proteins are divergent both in structure and function. A common class of J-proteins, represented by *E. coli* DnaJ, has three domains in addition to the J-domain: a glycine/phenylalanine-rich region, a zinc-binding region, and a C-terminal region. The two latter carboxy-terminal regions are involved in binding of nonnative protein substrates (Fig. 12c). Other J-proteins have domains that tether them to particular cellular locations, such as ribosomes (i.e. Zuo1 of yeast) or particular membranes (i.e. Pam18 of the

mitochondrial inner membrane or Sec63 of the endoplasmic reticulum membrane).

Nucleotide release factors Factors that destabilize the interaction of nucleotides with Hsp70 are important in the function of Hsp70/J-protein machinery. GrpE of the DnaK/DnaJ system is the best understood. It is a dimer that interacts with both the ATPase and substrate binding domain (Fig. 13). The interaction, which is stable in the presence of ADP, facilitates the release of this nucleotide. Orthologs of GrpE are found in mitochondria. However, structurally unrelated factors, such as Bag1 in the cytosol of mammals, serve as nucleotide release factors for other Hsp70/J-protein machineries.

The substrate polypeptide interaction cycle Interaction of Hsp70 with substrate polypeptides must be transient for them to carry out their biological function. This is accomplished by utilizing the great disparity in the interactions between Hsp70s and substrate polypeptides in the ATP- and ADP-bound states. Hsp70s bind substrate when in the ATP-bound state, as the on-rate is very rapid. The interaction is stabilized through hydrolysis of ATP. Hydrolysis is stimulated by at least two mechanisms. First, the interaction of polypeptide in the substrate binding site stimulates ATPase activity. Second, and more importantly, the J-protein partner stimulates ATP hydrolysis. The release of the substrate is modulated by the activity of nucleotide release factors (Fig. 11). Upon release of ADP, ATP rapidly binds, as it is typically present in much higher concentrations *in vivo*. This binding converts Hsp70 to a form having a rapid off-rate for substrate. Thus, substrate is released and Hsp70 is primed for another cycle of substrate interaction.

Multiple physiological roles of a single Hsp70 – example of mitochondria Hsp70s can function with more than one

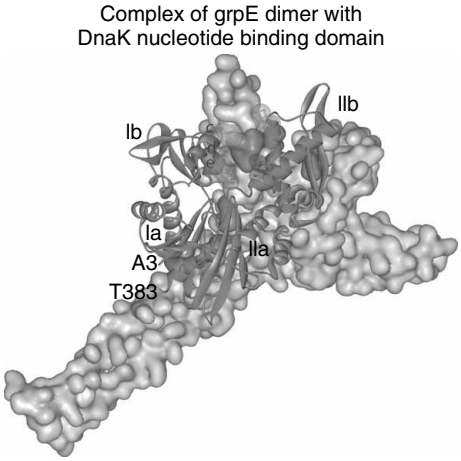

Fig. 13 Nucleotide exchange factor, GrpE, in space-filling representation (yellow and gold), complexed as a homodimer with the ATP binding domain of DnaK shown in ribbons (pdb 1DKG). The GrpE dimer interface is formed by two long α-helices (lower aspect) and, at the opposite end, a four-helix bundle. Interaction with the ATPase domain of DnaK occurs principally via a β-sheet of one of the monomers (protruding up from the long axis of GrpE, with sites of interaction colored orange) interacting mainly with DnaK's Ib and IIb subdomains. This interaction leads to a rotational displacement of IIb relative to the nucleotide-bound state, displacing bonds that would be formed with the base and ribose of ADP. The nucleotide binding site is thus disrupted by GrpE binding. Notably, in biochemical studies, GrpE binds to the ADP-bound and nucleotide-free states of DnaK with nanomolar affinity, but it is instantly dissociated from DnaK upon addition of ATP. Figure taken from Mayer, M.P., Bukau, B. (2004) Regulation of Hsp70 Chaperones by Co-chaperones, in: Buchner, J., Kiefhaber, T. (Eds.) *Protein Folding Handbook*, Part II, Chap. 15, Wiley-VCH, Weinheim, pp. 508–548. (See color plate p. xxviii.)

J-protein partner, which in part explains the functional diversity amongst these Hsp70-based machineries. For example, the soluble Hsp70 of the mitochondrial matrix, Ssc1, not only works with the J-protein of the mitochondrial inner membrane, Pam18, in the translocation of proteins from the cytosol into the matrix space of mitochondria but also functions with the soluble J-protein, Mdj1, in the folding of the newly imported proteins and refolding of partially denatured proteins. The specialized role of Pam18 in import is in part a function of being precisely tethered to a particular cellular location. Pam18 and Ssc1 are themselves independently targeted to the translocon of the inner mitochondrial membrane through which polypeptides are imported. This targeting ensures a high concentration of Hsp70/J-protein ready to interact with the unfolded polypeptide as it enters the matrix. (Similarly the cytosolic Hsp70/J-protein pair of yeast, Ssb and Zuo, localize near the exit of the tunnel of the ribosome, positioned to interact with emerging nascent polypeptides.) Second, the Ssc1/Pam18 machinery serves as an example of the adaptation of the ability of Hsp70s to bind short hydrophobic segments of polypeptide for biological roles other than protein folding. The interaction with translocating polypeptides serves as the driving force for the translocation of the bulk of cytosolically synthesized proteins across the inner membrane. This process utilizes the regulation of transient interactions by both a J-protein partner and a nucleotide release factor for cycles of interaction with the polypeptide, preventing backward slipping toward the cytosol.

In addition to gaining specialization through tethering to specific cellular targets, there are examples of specialization of substrate specificity. The best studied example is that of the specialized Hsp70/J-protein pair involved in the biogenesis of Fe−S cluster proteins: HscA(Ssq1)/HscB(Jac1) in bacteria (yeast). Apparently only one substrate exists for this machinery. The folded scaffold protein on which an Fe−S cluster is built, IscU (Isu), binds both the J-protein and the Hsp70 of this machinery. How these interactions promote Fe−S cluster assembly has yet to be resolved. Such interaction of the Hsp70 system with a native structured component also occurs in the case of λ DNA replication where DnaK pries apart a protein–protein interaction, and in regulation of the heat shock response where DnaK binds sigma 32 itself regulating its lifetime, as discussed earlier.

4.3 Small Heat Shock Proteins

Additional components that are σ^{32} inducible are the small Hsps, members of a ubiquitous family of proteins whose small subunits assemble into large oligomeric assemblies, containing 9 to more than 30 subunits, able to bind nonnative proteins at their surface via hydrophobic contacts, protecting them from aggregation. The subunits range in size from 16 to 40 kDa and invariably contain a C-terminal 90 amino acid domain, the so-called α-crystallin domain. Included in the sHsp family are the lens α-crystallins, which play a key role in preventing protein aggregation that would result in cataract formation. Multiple sHsp genes are found in most species, the products localizing typically to the cytosol, but under some conditions to the nucleus, and in some species also to organellar compartments. The nature of the heterogeneity of sHsp structure and function within any given

cellular compartment remains to be understood. In many cases, coassembly of different sHsp subunits occurs into any given sHsp complex within a given cellular compartment, further complicating functional evaluation.

Two different sHsps that form regular assemblies have been resolved crystallographically (Fig. 14a), one from an archaeon, *Methanococcus jannaschii*, and the other from wheat, showing two distinct types of assembly, the former a 24mer, soccer-ball like structure with a hollow core and side windows, with an outer diameter of 120 Å, 432 symmetry, and monomers all in equivalent structural environments, effectively four trimers of dimers. By contrast, the wheat structure is a 12-subunit assembly composed of two stacked six-membered discs, each a trimer of dimers, 95 Å in diameter with a hollow cavity. For both of these structures, there are nonresolving sequences from the nonshared N-terminal regions that may localize within the hollow cavities. Yet both reveal the conserved C-terminal α-crystallin domain, a β-sheet sandwich. A basic dimer building block of these sHsps is formed from longitudinal stacking of the α-crystallin domains of two subunits. The nonconserved N-terminal regions then contribute to the unique assemblies that are formed. By contrast with these two crystallized sHsps, many other sHsps form assemblies that are heterogeneous in subunit number and organization as judged from EM studies.

The nature of substrate binding by sHsps remains to be fully understood, but properties of subunit dissociation

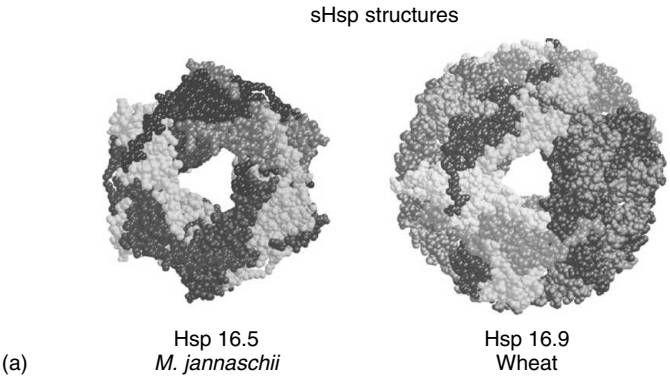

Fig. 14 Small heat shock protein structures and mechanism of action. (a) Crystallographic models of small hsps from archaeon *M. jannaschii* and wheat (pdb 1SHS, Kim et al, 1998 and 1GME, van Montfort et al, 2001, respectively) are shown, with coloring of individual subunits. (b) Mechanism of action of small hsps. Under heat stress, shsps undergo accelerated subunit exchange and structural rearrangement, associated with presumed exposure of hydrophobic surfaces that recruit nonnative polypeptides, forming substrate-chaperone complexes. Such action prevents aggregation of the nonnative polypeptides that occurs otherwise. Upon relief of heat stress, bound proteins are released and can be assisted to refold by the hsp70 system. Figure taken from van Montfort, R., Slingsby, C., Vierling, E. (2002) Structure and function of the small heat shock protein/α-crystallin family of molecular chaperones, *Adv. Protein Chem.* **59**, 105–156.

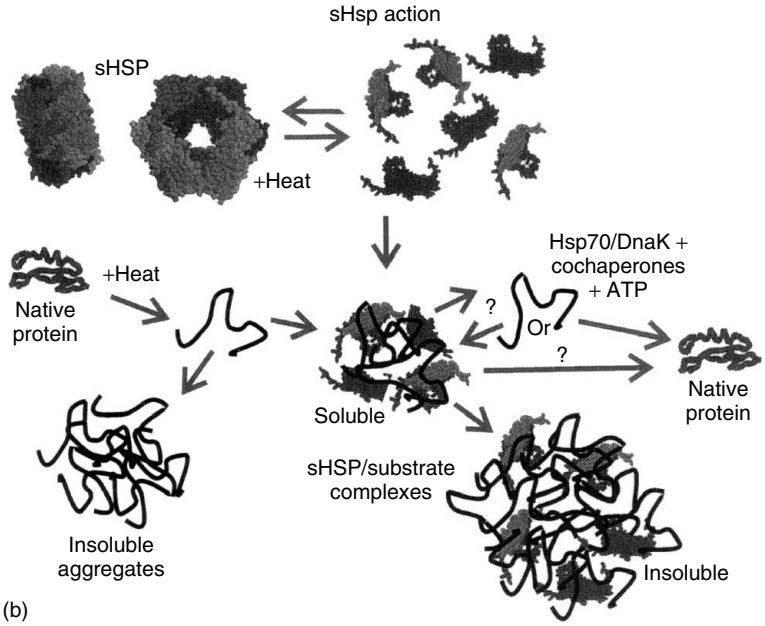

Fig. 14 (*Continued*)

and exchange, and/or structural rearrangement of subunits under stress conditions appear to figure in exposing hydrophobic binding sites that are otherwise buried as viewed in the X-ray structures (Fig. 14b). Both N-terminal sequences and a conserved motif in the α-crystallin domain of the wheat sHsp have been implicated by Bis-ANS binding experiments, the latter sequence noted to be buried in the structure as viewed by X ray, necessitating subunit dissociation or rearrangement to enable surface exposure.

Experiments *in vitro* reveal that complexes between sHsps and substrate proteins form larger-order heterogeneous structures, with multiple substrate proteins able to be bound in nonnative protease-susceptible form by an assembly of sHsps. Such binding of substrate serves to prevent stress-exposed proteins from aggregation. Recovery of the native form of bound substrate proteins ultimately requires release from the sHsps followed by refolding, assisted in many cases by other molecular chaperones, for example, the Hsp70 and chaperonin systems.

In addition to a protective role under stress and a role in lens maintenance, sHsps have been implicated in maintenance of the actin and intermediate filament cytoskeletons. Consistent with such a role, mutation of αB-crystallin has been found in a desmin-related myopathy. Accumulation of αB-crystallin in aggresome-like structures with staining properties of amyloids has also been observed in heart muscle of mice carrying the same mutation. An involvement of sHsps in blocking apoptosis has also been indicated by observation of binding to holocytochrome *c* released from mitochondria, blocking its activation of caspases.

5
Other Heat-inducible Components

The early studies of Neidhardt and VanBogelen and more recent ones have identified a number of other components that are induced by heat shock.

5.1
Hsp90

This chaperone is present in high abundance in the eukaryotic cytosol (~2–5% soluble protein), in the ER as the homolog GRP94, and in the bacterial cytoplasm (HtpG); in all three locations it is stress inducible. This suggests that it plays a general role in protecting misfolding proteins, but, despite the availability of both conditional mutants and pharmacological inhibitors, such action has not been demonstrated to date in any cellular context. Rather, a more specialized role has been identified in a late stage of the folding of several classes of substrate protein. This was first uncovered for Hsp90 in the eukaryotic cytosol, where, functioning in the context of multiprotein complexes containing a variety of ''co-chaperone'' components, Hsp90 binds near-native conformations and assists the final folding of a variety of ''client'' proteins including nuclear receptors, such as the glucocorticoid, progesterone, estrogen, and androgen receptors, and protein kinases such as src and PKB/Akt. In the case of the receptors, action by Hsp90 complexes is required in order to attain a ligand-activatable state, and the step of ligand binding releases such receptors from Hsp90 complexes in active forms that carry out transcriptional regulation. In the case of kinases it appears that binding of the catalytic domain is involved, potentially of the activation loop segment, enabling these molecules to assume an active state. A similar maturational action in the ER has been resolved for GRP94, assisting the biogenesis of, for example, ErbB2, immunoglobulins, and MHC class II molecules, but GRP94 also participates in binding peptides that will be presented by Class I molecules. Notably, in contrast with Hsp90 in the cytosol, the action of Grp94 in the ER appears to occur in the absence of associating cochaperones.

The multiprotein complexes involved in cytosolic Hsp90 action include such cochaperone components as Hsp70 or Hsp40 which likely mediate initial binding of client protein substrates prior to binding by Hsp90; Hip which modifies Hsp70 ATP binding activity; immunophilins bearing peptidylprolyl isomerase activity, such as Cyp40 and FKBP51/52; Hop/Sti1 a TPR (tetratricopeptide) repeat-containing ''adaptor''/scaffold protein able to bind EEVD motifs at the C termini of Hsp70 and Hsp90; Cdc37 implicated in recruiting client kinases via its N terminus to Hsp90, which it binds through its C terminus; and p23/Sba1 which binds Hsp90 in the ATP-bound dimeric state and which appears to play a role in enabling productive release of client proteins. The formation and maturation of these multiprotein complexes is associated with an ordered binding and release of the specific cochaperone components, and this appears to regulate ATP binding and hydrolysis by Hsp90, which is in turn coupled with the conformational activation and release of client proteins.

For example, ''early'' steroid receptor complexes contain Hsp70 and Hop/Sti1 but lack Hsp90, whereas ''later'' ones contain Hsp90, immunophilins, and Sba1 but lack Hsp70 and Hop/Sti1. It is ''intermediate'' complexes that are involved with client protein recruitment to Hsp90, inhibited in ATP hydrolysis in such complexes

by the presence of Hop/Sti1. Departure of Hop/Sti1 and binding of immunophilins, however, then allows Hsp90 in a ''late'' complex to bind ATP, maintaining the client protein in an activatable state. This most likely involves ATP-bound Hsp90, producing or maintaining an open hydrophobic ligand binding pocket in the receptor molecule, producing a conformation that allows steroid ligand binding. The site(s) on Hsp90 that is involved in forming such physical association with client proteins remains to be defined, but presumably hydrophobic surfaces in the chaperone itself are involved, with candidate surfaces identified in crystallographic studies in both the middle and C-terminal domains. An open cavity formed between two outwardly curved regions of the molecule, dimerized through the C terminus (see Fig. 15), could be a site for localization of the bound substrate. Once ATP is turned over by the very slow N-terminal ATPase domain of hsp90 ($\sim$0.2 min^{-1}), the molecule may assume a more closed state, and these hydrophobic regions may become buried, driving release of the client receptor molecule, regardless of whether steroid hormone ligand has been bound.

Given the nature of its client proteins, involved with cellular signaling and growth control, hsp90 has been suggested to potentially function as an evolutionary ''capacitor'' that allows mutant versions of signaling kinases or receptors to remain functionally stabilized under normal conditions such that under unfavorable conditions, where hsp90 may be recruited to misfolded states, these mutant components may then become phenotypically expressed and may specifically allow survival of an ''evolved'' organism. Evidence in support of such a model comes from stress treatment of flies and plants, as well as specific inhibition of hsp90 by ansamycin drugs or RNAi – such treatments prompt exhibition of phenotypes that reflect uncovering of mutations lying in these pathways. In sum, the idea is that if hsp90 becomes tied up with stress response it is no longer able to suppress the misbehavior of mutants in critical signaling pathways, leading to a phenotype.

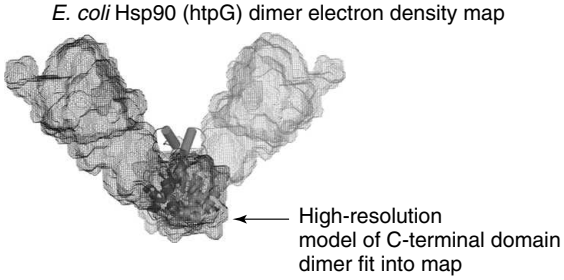

Fig. 15 Electron density map of intact *E. coli* HtpG (hsp90) dimer, illustrating the potential canyon between monomers in which nonnative substrates may become bound. Contact between the HtpG monomers (in the absence of nucleotide) occurs through their C termini, for which a high-resolution crystal structure has recently been solved (pdb 1SF8). Notably, structures have also been solved for the N-terminal ATP binding domain (also the site of ansamycin drug binding) as well as middle region of eukaryotic hsp90. Here, in the high-resolution structure of the dimer of HtpG C termini, the dimer interface involves a four-helix bundle. Two additional helices point out of density and their hydrophobic character and position within the ''jaws'' of the dimer, as well as functional studies, suggest potential involvement in substrate binding. Additional hydrophobic sequences, however, from the middle region have also been implicated (see text). Figure taken from Harris, S.F., Shiau, A.K., Agard, D.A. (2004) The crystal structure of the carboxy-terminal dimerization domain of htpG, the *Escherichia coli* Hsp90, reveals a potential substrate binding site, *Structure* **12**, 1087–1097.

5.2
Hsp33 and Oxidative Stress

Another heat responsive component that also counters oxidative stress, manifesting general chaperone activity as reflected by binding of a host of nonnative proteins under stress conditions, is the protein known as hsp33. Under normal cellular conditions hsp33 is abundant but occupies a reduced and inactive state, coordinating zinc through its four conserved cysteines (see Fig. 16), but under conditions of oxidative stress the zinc is released, allowing the cysteines to form disulfide bonds, associated with a conformational switch of the protein that allows its dimerization, exposing surfaces that bind nonnative polypeptides. Such action appears to be further enhanced by exposure to the added stress of heat, which strongly induces the abundance of hsp33. Relief of stress and return to reducing conditions allow release of substrate and dissociation of the hsp33 dimer (see Fig. 16). Released substrate is assisted with reaching native form by action of the hsp70 system. A recent study suggests that inactivation of DnaK occurs

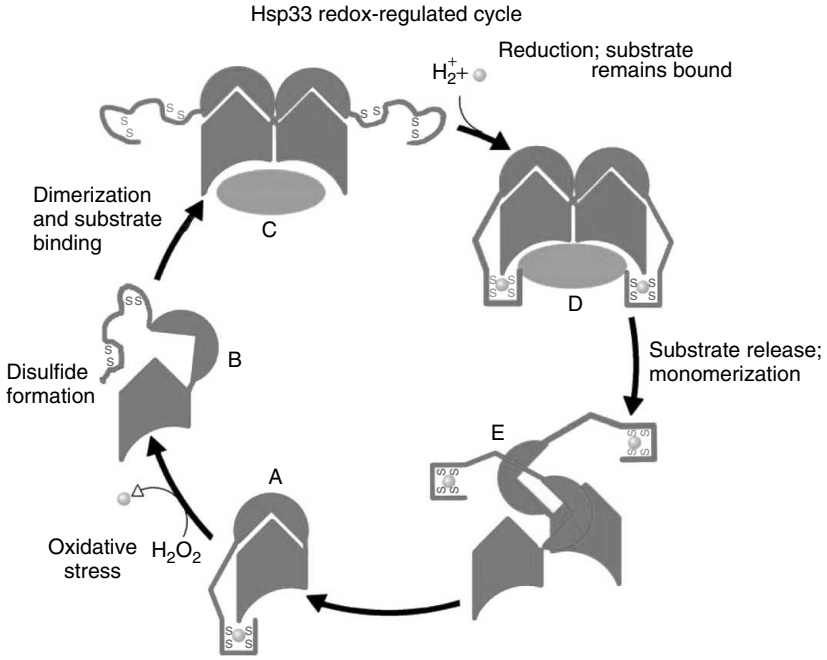

Fig. 16 hsp33 chaperone cycle. Under oxidative stress conditions, four cysteine residues in the C-terminal region of hsp33 switch from a zinc-coordinated state to forming a pair of disulfide bonds, associated with hsp33 dimerization and with exposure of a binding surface for nonnative polypeptides. Upon return to normal conditions, these steps are reversed and substrate proteins are released. They are subsequently acted on by the hsp70 system to regain the native state. Figure taken from Janda, I., Devedjiev, Y., Derewenda, U., Dauter, Z., Bielnicki, J., Cooper, D.R., Graf, P.C.F., Joachimiak, A., Jakob, U., Derewenda, Z.S. (2004) The crystal structure of the reduced, Zn^{+2}-bound form of the B subtilis Hsp33 chaperone and its implications for the activation mechanism, *Structure* **12**, 1901–1907.

under conditions of both heat plus oxidative exposure, a condition where hsp33 becomes the active chaperone; the roles are then reversed as normal conditions are resumed.

5.3
Hsp15 and Free 50S Ribosomal Subunits

This abundant protein is highly heat inducible and binds with high affinity to free 50S ribosomal subunits bearing nascent chains, as distinct from intact 70S ribosomes. A role in recycling 50S subunits bearing a nascent chain has been proposed. hsp15 appears to most immediately recognize an RNA moiety.

5.4
FtsJ

FtsJ also appears to bind nucleic acids. It also carries a methyltransferase fold, and its ability to methylate 23S rRNA within 50S ribosomal subunits of *E. coli* has been demonstrated both *in vivo* and *in vitro*. Null mutants exhibit an altered ribosome profile and growth defects. A condition of human X-linked mental retardation has recently been associated with defects in an FtsJ homolog whose yeast counterpart is involved in methylation of tRNA anticodon loops. Thus, the human condition likely results from defective translation.

6
Chaperone-protease Pairs – ClpP, HslV, and Lon, and Associated ATP-dependent Chaperone Unfoldases, ClpA, ClpX, and HslU

A set of proteases is also heat inducible, enabling the efficient degradation under stress conditions of damaged proteins. In the bacterial cytoplasm and mitochondrial compartment, these include the cylindrical proteasome-like proteases ClpP, HslV, and Lon. These components strongly resemble the eukaryotic proteasome in architecture and overall action, and HslV, in particular, resembles it in the mechanism of proteolysis. In all cases, access to these proteases occurs via narrow openings in their terminal ends, allowing only those substrates that have been selected and unfolded to enter, effectively producing a compartment within a compartment, that is, a proteolytic chamber within a cellular compartment (Fig. 17). The selection, unfolding, and translocation of substrates in all of these cases is governed by a cylindrical chaperone/unfoldase moiety, also housing a narrow central passage, either in a separate molecule that coaxially associates with the protease (ClpA and ClpX with ClpP, and HslU with HslV), or, in the case of Lon, the unfoldase moiety resides within the same protease cylinder. The chaperone moiety recognizes the specific proteins to be targeted for degradation via specific elements, and, through the action of ATP binding and hydrolysis, couples unfolding of the substrate protein with translocation down the axial passageway into the protease (Fig. 17).

6.1
Substrate Recognition and Translocation Mediated by the Chaperone Moiety

It is the step of recognition that confers specificity, triggering the subsequent steps of unfolding and degradation, and such recognition involves somewhat different strategies between prokaryotes and eukaryotes. In prokaryotes, such hsp100 unfoldases as ClpA and ClpX, both hexameric ring assemblies, recognize short-terminal

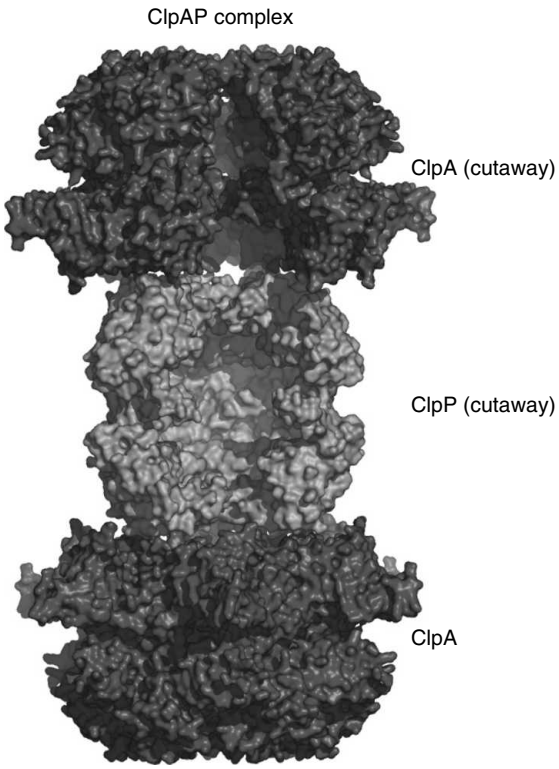

Fig. 17 ClpA–ClpP complex, illustrating the central channel pathway taken by substrate proteins as they are unfolded by the hsp100 chaperone ClpA (green) in association with ATP hydrolysis and translocated into the protease ClpP (blue), where they are degraded. Red regions inside ClpA designate loop segments at the level of the D2 ATPase domain of each identical subunit that has recently been shown to be involved with both binding and ATP-driven translocation of substrate proteins. Yellow inside ClpP designates the serine proteolytic active sites. Model generated by docking of a hexameric model of ClpA derived from the crystal structure of a monomer (1KSF) (employing the structure of the intact p97 hexamer as a guide – 1OZ4), with the crystallographic model of ClpP (1TYF). (See color plate p. xxxix.)

amino acid sequences of proteins to be unfolded and degraded. For example, an 11 amino acid sequence, ssrA, is attached to the C terminus of nascent chains that become arrested in translation at the ribosome, and this sequence is specifically recognized by both ClpA and ClpX. In the latter case, a ''delivery'' agent known as SspB can bind the ssrA-tagged substrate at the ribosome, lodging it in a relatively extended shallow groove, and acts to deliver the substrate to ClpX. Terminal recognition elements like ssrA appear to be recognized by the hsp100 cylinders themselves, either by flexible (usually N terminal) domains at the top of the cylinders or by loop elements inside their central channels. Delivery agents like SspB are recognized by the flexible N-domains, and in binding them, may serve to deliver the tag elements directly to the central channel recognition elements. The action of ATP hydrolysis then appears to drive pulling movements associated with translocation of substrates, tagged end first, down the axial channels, associated with unraveling and unfolding of the substrate protein's tertiary structure.

In eukaryotes, the system of recognition of proteins to be unfolded principally involves the attachment of the 79 amino acid moiety known as *ubiquitin* to either the N terminus or to lysine side chains of the target protein, mediated by a system of conjugating enzymes (E2s) and ligases (E3s). Once a protein is multiubiquitinated, it is efficiently bound by the 19S ''cap'' structure of the

proteasome, which subsequently employs a six-membered ring of ATPases at its base, contiguous with the 20S core protease particle, to mediate unfolding of the recognized protein, most likely using the same mechanism as that being defined for the prokaryotic AAA+ unfoldases just described.

6.2 Proteolytic Components

On the part of the proteolytic cylinders, unfolded polypeptides arriving from the coaxially associated unfoldases see a local concentration of protease active sites that is molar in concentration, assuring efficient cleavage by active sites lining the protease cavity walls. A variety of chemical strategies for peptide bond cleavage are utilized by the proteasome, but one that is novel, employed by the class of Ntn hydrolases including HslV, involves N-terminal threonine, acting as nucleophile via its side-chain hydroxyl group, attacking the carbonyl of the scissile peptide bond. This mechanism acts both to remove the propeptide from the proteasome subunit precursor and also to cleave bonds within substrates. In the latter case, the free amino group of the subunit strips the proton from the hydroxyl group of the active threonine side chain, activating the nucleophile. By contrast, in the case of ClpP, a serine proteolytic site is employed, with a classic Ser-His-Asp triad, but one positioned in a cleft formed between two β-strands, one in a ''head'' structure and the other in a ''handle'' of each subunit, the site facing the central cavity of the protease.

It is of interest that many of the prokaryotic unfoldases are composed of six-membered rings, as is the base of the proteasome, while the proteolytic cylinders with which these components associate are composed of seven-membered rings. Such symmetry mismatch is intriguing, potentially allowing for sliding or rotational movements of one component relative to the other, or allowing for modulation of the affinity of the components for each other. Notably, in the case of the ClpA and ClpX proteins, it is loop elements at the bottom aspect of their subunits that make contacts with a continuous ring of hydrophobic surface in the end surface of ClpP to mediate interaction between these components. Yet symmetry mismatch does not seem to be universal amongst these complexes as, for example, HslU–HslV are hexamer–hexamer assemblies, and other proteases, like Lon, already contain a chaperone moiety built within each of the proteolytically active subunits (see the following section).

6.3 HslU–HslV

HslV is also a double ring protease, composed of six-membered rings, whose active sites, containing a catalytic N-terminal threonine, most closely resemble those of the eukaryotic proteasome. Here the associating chaperone ''unfoldase,'' HslU, also an AAA+ hexameric ring, aligns subunit to subunit with HslV. Each subunit of HslU exposes at its open end a flexible antiparallel segment known as an *I domain*. These domains, emanating from the ATPase domains of the subunits, collectively appear as tentacles that seem likely to be involved with capturing substrate proteins and potentially transferring them into the axial passageway of HslUV. Crystallographic studies show that association of HslU with HslV leads to allosteric adjustments at the

HslV active sites that serve to activate the protease activity of HslV.

6.4 Lon

Lon protease appears to function similar to the ClpP and HslV systems, except that each subunit of this hexameric ring assembly contains built into it an N-terminal domain, an AAA+ unfoldase domain, and a protease domain. While these elements are covalently linked, the sequence of events of recognition of substrate, translocation and unfolding, and degradation, seem likely to be the same. The protease domain has recently been crystallized, revealing an axial pore of 18-Å diameter giving rise to a distal concave surface in which is situated a serine-lysine active site dyad flanked by residues including a threonine which may functionally resemble the Aspartate in Ser-His-Asp triads and NHs that may stabilize the oxyanion. Interestingly, a similar X-ray structural analysis of an archaeal lon protease domain (*M. janaschii*) revealed a more classic Ser-Lys-Asp triad.

7 Disaggregases – Prokaryotic ClpB and Eukaryotic Hsp104

The ClpX and ClpA proteins have relatives, ClpB and hsp104, which are strongly heat-induced components of the bacterial cytoplasm, and yeast and plant cytosols, respectively, with architecture resembling that of ClpA, a ring of six identical subunits with a stacked domain structure of N-terminal flexible domains at the top of the cylinder and two AAA+ ATPase domains. Here, however, there is no protease partner, and there is also an additional striking structural feature; long coiled-coil ''propeller'' domains emanating from the first AAA+ domain at the outside of each of the six subunits at the midsection of the cylinder. These proteins have a unique ability to dissociate protein aggregates in the presence of the hsp70 (DnaK) system and ATP. The nature of such cooperation and role of the coiled-coil elements remain unclear, but it seems that hsp70 may be involved with enabling aggregated subunits to be bound or threaded through the central channel of ClpB, which thus unfolds them and allows them a chance to properly refold in the presence of the hsp70 and hsp60 systems.

8 Periplasmic Proteolytic System – HtrA Proteases DegP and DegS

Regulated proteolytic steps like those carried out by the Clp system, the proteasomal system, HslUV, and Lon occur in cellular locations that contain millimolar concentrations of ATP, needed to drive the unfolding and translocation of substrate proteins mediated by the AAA+ moieties of these proteases. Yet the cell has apparent need for the same strategy of regulated proteolysis in providing protein quality control to compartments that do not have access to ATP, for example, the bacterial periplasm and mitochondrial intermembrane space. In these compartments, it appears that a similar protease system is employed, preserving a strategy of caging the active sites inside an oligomeric assembly, but with substrate access not dependent on ATP. This family of proteases, called the *HtrA proteases* (high temperature requirement), is comprised of subunits, each containing a serine proteolytic domain and one or two C-terminal PDZ domains.

8.1 DegP

The notion that chaperone and protease activities are brought together in HtrA components, as with the ATP-dependent ones, is supported by structure and functional studies of DegP and of the more specialized membrane-anchored DegS. In functional studies of DegP, it was observed that at low temperatures this component has little or no proteolytic activity, yet it exhibited ability both *in vivo* and *in vitro* to assist the folding to native form of such periplasmic enzymes as malS. At heat shock temperatures, however, DegP protease activity became activated as observed *in vitro*, and recovery of native malS was reduced *in vivo*, as the apparent result of proteolytic turnover of molecules whose proper folding did not occur at the higher temperature. X-ray structural study of DegP followed, providing indications of how the machine might be functioning (Fig. 18). DegP is a hexamer composed of two oppositely positioned and loosely connected tight trimers of protease domains, with the PDZ domains packed loosely at the outside aspect forming mobile side-walls that can serve as gates for substrate entry into a central cavity. The oppositely positioned protease trimers are connected to each other by three pillars of polypeptide loop segment extending from each protease domain into the active site of a protease domain in the opposite ring. Two molecular forms were observed in the crystals, an open one with lateral openings between the pillars into the proteolytic cavity, wherein the PDZ domains lie at the lateral aspects of the trimers, and a closed form where the PDZ domains lie at the equatorial aspect blocking access to the cavity. These geometries further support that it is lateral gating that is involved with entry into the DegP cavity. The two PDZ domains themselves differed in character, one with an open groove, available to accept a segment of polypeptide as an added strand between a resident one and α-helix as in canonical PDZ motifs, and the other with an already occupying resident segment that may be mobilized under conditions of substrate binding but which could then conceivably displace substrate in the context of entry into the protease. The proteolytic cavity itself, $\sim$15 Å in height and $\sim$45 Å in diameter contains patches of hydrophobic surface at its ceiling (and floor), which may be involved with binding nonnative substrate entering the central cavity.

Concerning the protease sites, in the crystals obtained, transferred to 4°, the protease would be expected to be inactive and, consistently, the serine proteolytic sites, as classic trypsin-like sites formed between two orthogonal β-barrels, were indeed found to be distorted, with twists of the active site loops distorting the catalytic triad, oxyanion hole, and S1 specificity pocket. The catalytic sites were also blocked. The molecular nature of the thermal switch in DegP thus remains to be resolved, but there must be significant readjustment of the loops both extending from one trimeric ring into the other, and also locally of the active site loops. Concerning the nature of recruitment to the protease sites, it seems that either already unfolded substrates are recruited by the PDZ domains through the cavity wall into the proteolytic central cavity or that PDZ action and threading into the cavity mediates an unfolding action that favors proteolysis. Perhaps the PDZ domains can exert a pulling action akin to that suggested for the loops in the central channel of ClpA.

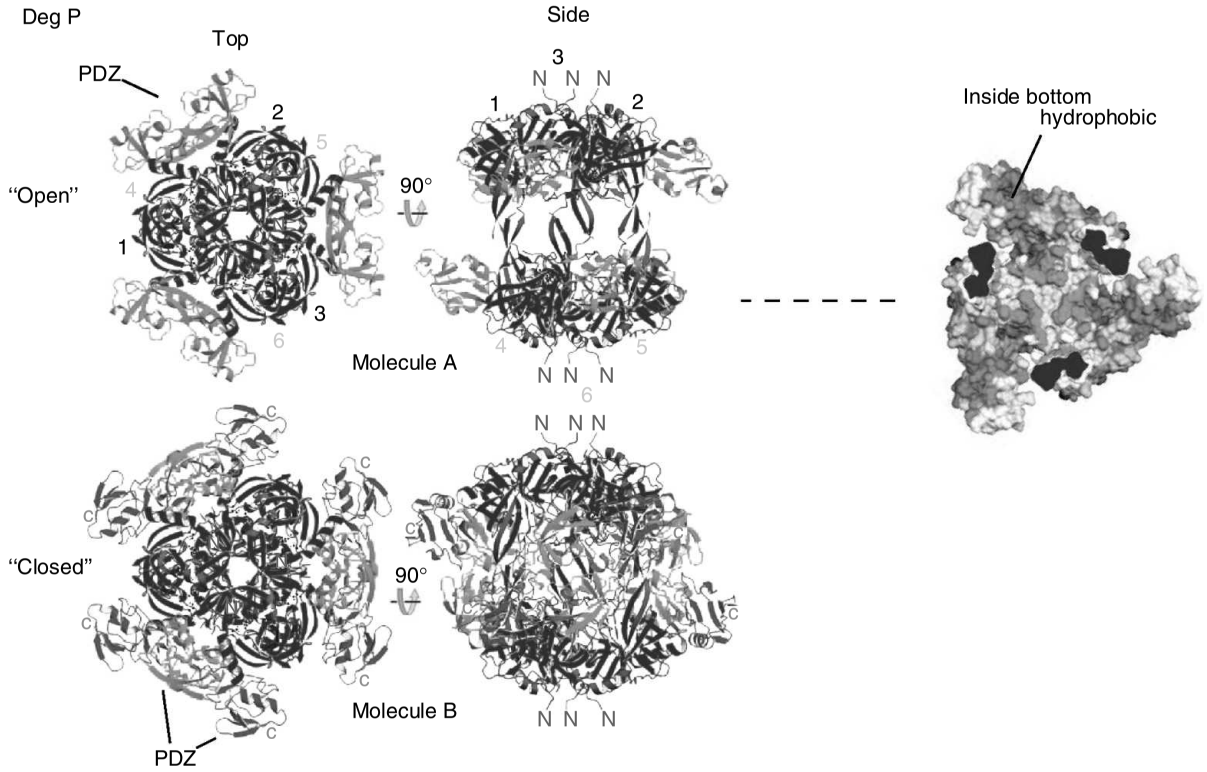

Fig. 18 Structure of the *E. coli* periplasmic protease DegP. The protease is composed of two trimeric protease rings facing each other (green) interconnected by struts of β-strand that enter the protease active sites and regulate activity (see text). The protease domains are flanked by PDZ domains (yellow and orange) that are involved with capture and perhaps unfolding of substrate proteins. The substrates are then transferred in an ATP-independent fashion through the sidehole aspects of the assembly into the proteolytic cavity, the inside of which contains hydrophobic surface at its terminal inside aspects, shown in yellow, likely involved with "guiding" substrate into the serine proteolytic sites. Figure taken from Krojer, T., Garrido-Franco, M., Huber, R., Ehrmann, M., Clausen, T. (2002) Crystal structure of DegP (HtrA) reveals a new protease-chaperone machine, *Nature* **416**, 455–459, pdb 1KY9. (See color plate p. xliv.)

8.2 DegS

In the case of the related DegS, additional glimpses of regulatory behavior of this class of component have been possible. Here, the serine proteolytic active sites were also found to be structurally nonorganized in the absence of substrate protein, but when a C-terminal peptide presented by unfolded Omp proteins became bound to the PDZ domains, adding a β-strand to one edge of the β-sheet of the PDZ domain, then the DegS active sites became reorganized into the active Ser-His-Asp triad. Thus, based on the behavior of DegS, it seems even more apparent that the PDZ domains are involved with substrate recognition, and that such recognition can directly influence the conformation of the proteolytic sites at least in DegS.

While DegP and DegS have very similar structural arrangements, their physiological roles differ considerably. DegP is a soluble periplasmic protease that appears to have broad substrate reactivity while DegS has a dedicated role in sensing specifically the free C termini of Omp proteins in the periplasmic space, termini that are normally buried but made specifically available by protein misfolding. Such binding, as described in Fig. 3, activates the protease of DegS, enabling cleavage of the transmembrane protein, RseA, followed by a second cleavage event mediated by YaeL, which leads to release of σE, the periplasmic stress-responsive sigma factor, from RseA, enabling transcriptional activation of periplasmic heat shock components such as DegP.

8.3 Omi

Finally, a mammalian homolog of DegP (Omi), residing in the mitochondrial intermembrane space, has been observed to be affected in a recessively inherited mouse motor neurodegeneration mutant known as *mnd2*. Purified mutant protein was devoid of proteolytic activity against casein. Omi appears to have a role in apoptosis, as it is released along with cytochrome *c* during this process, and it can degrade the class of proteins that are inhibitors of apoptosis (IAPs). This degradation activity was also defective. Interestingly, however, deletion of the PDZ domain from the mutant protein partially restored activity to the mutant, suggesting that the mutation, involving one of the large active site loop structures, affects substrate access to the active site. *In vivo*, loss of the protease activity of Omi increased the susceptibility of mitochondria in affected fibroblasts to a permeability transition of the membranes triggered by Ca^{+2}, associated with loss of membrane potential and with release of proapoptotic proteins. Thus, loss of a quality control function of this protease, particularly in striatal neurons, may lead to induction of the permeability transition, both reducing mitochondrial respiratory function and triggering release of apoptotic proteins leading to cell death. Consistently, mitochondrial disintegration is observable early during neuronal degeneration.

Keywords

Extended Shuttling Model
The hypothesis for protein import into peroxisomes whereby the PTS receptor enters the matrix where dissociation from cargo occurs.

Glycosome
The peroxisome in trypanosomatids, which houses several enzymes of the glycolytic pathway.

Glyoxysome
A subclass of peroxisomes in which the conversion of fatty acids to Krebs cycle intermediates is a key function.

Microbody
The original term for the peroxisome; still used as the morphological equivalent.

mPTS
The targeting information in peroxisome integral membrane proteins.

PBD
Peroxisomal biogenesis disorder. A patient afflicted by a PBD has a defective PEX gene.

Peroxin
A product of a PEX gene.

Peroxisome
An organelle, 0.2 to 0.5 μm in diameter, distinguished by a single membrane, a dense matrix, and common biosynthetic features; most are ovoid or spherical, contain flavin oxidases and catalase, and participate in lipid metabolism; many contain crystalline cores.

PEX Gene
A gene encoding a protein that functions in peroxisomal biogenesis. Before 1996, when nomenclature was unified, such genes were also known as *PAS*, *PEB*, or *PER*.

PTS
Peroxisomal targeting signal. Most matrix proteins contain a PTS1, a tripeptidyl sequence of which SKL is the prototype, at their extreme carboxy termini. A few others contain a PTS2 at or near their amino terminus.

Zellweger Syndrome
The most serious of the PBDs, characterized by facial dysmorphism, calcific stippling of cartilage, liver and renal disease, and nerve demyelination.

Peroxisomes comprise a family of organelles that are found in virtually every eukaryotic cell; they contain a single membrane enclosing a dense matrix. Crystalloid cores may also be present. While the functions of peroxisomes in some organisms and tissues can be highly specialized, most peroxisomes perform crucial reactions in the biogenesis and degradation of lipids. Many metabolic reactions within peroxisomes are catalyzed by flavin oxidases that generate hydrogen peroxide (thus the name ''peroxisome''); catalase and other antioxidants exist in the matrix to protect the cell from oxidative damage. While isolated cells can survive without peroxisomes, animals and plants require them. Peroxisomes provide substrates for several developmental programs. Defective peroxisomes cause serious disease and early death in humans. Peroxisomes can arise from fission of preexisting organelles, as well as from a less understood *de novo* pathway that originates in the endoplasmic reticulum. Most matrix proteins fold and assemble in the cytosol and then are targeted to peroxisomes via chaperones and shuttling receptors. Great progress has been made in understanding protein import into peroxisomes, but important mysteries remain.

1 Introduction

A novel organelle was identified by Rhodin in electron micrographs of mouse kidney brush border in 1954. *Microbodies*, as they were termed, consisted of a single membrane surrounding a finely granular matrix and were 0.5 μm or smaller in diameter. Similar organelles in liver parenchymal cells, except those also containing crystalloid cores, were reported two years later by Rouiller and hypothesized to be mitochondrial precursors. Concurrent with these observations, the laboratories of de Duve and Baudhuin began the biochemical purification of lysosomes, particles that contained hydrolytic enzymes. Other enzymes, namely, catalase, uric acid oxidase (uricase), and a D-amino acid oxidase were initially fractionated with the hydrolytic enzymes but later could be purified away from them. In 1960, these nonlysosomal enzymes were ascribed to microbodies and shortly thereafter, in 1965, de Duve proposed a new name for the particle, ''peroxisome,'' in recognition of hydrogen peroxide, the metabolic intermediate between the oxidases and catalase.

In the next decade, particles of similar morphology were found in many diverse cell types. In trypanosomes, an organelle was identified that contained, unexpectedly, several enzymes of the glycolytic pathway and thus were named *glycosomes*. In plant seedlings and in filamentous fungi, a different organelle, termed the *glyoxysome*, was described that contained enzymes of the glyoxylate cycle, in which acetyl-CoA could be converted to succinate, thereby linking the product of fatty acid oxidation with carbohydrate metabolism. In methylotrophic yeasts, microbodies were described that could proliferate to a huge extent, virtually hijacking the cytoplasm; these organelles performed the initial steps of methanol assimilation. Since these diverse organelles performed such different functions, it was not at all clear that they were related. This issue was finally

resolved after Gould, Subramani, and colleagues reported the first peroxisomal targeting signal, and it became clear that this motif was shared among matrix proteins of microbodies from all of these sources. The close relationship among these structures was confirmed as similar proteins involved with peroxisomal biogenesis were identified in all of these cell types.

The origin of peroxisomes has been a fascinating area of research since their identification. The first peroxisome may have been a prokaryotic endosymbiont that gave the host a selective advantage in an oxygen-dominated environment, but the lack of a genome and the ancient nature of this event, if it occurred at all, may make this hypothesis impossible to validate or disprove. Early electron microscopic analysis suggested that peroxisomes arose as buds from the endoplasmic reticulum. By 1980, however, it was clear that peroxisomes can arise by fission, and it was thought that a peroxisome was necessary for the generation of new organelles. The pendulum has now settled midway between these theories: the consensus at present is that peroxisomes can develop both from preexisting peroxisomes and from elements (of mysterious identity at present) of the endoplasmic reticulum.

2 Common Structural and Functional Motifs

Typical peroxisomes in electron micrographs are spherical or ovoid with a diameter of 0.2 to 0.5 μm. As a general rule, peroxisomes distribute evenly throughout the cytosol and appear as uniform puncta by optical microscopy using fluorescent or antibody tags. Yeast contain a dozen or fewer puncta, mammalian cells contain several hundred. They are sometimes clustered, perhaps as a result of recent fission events, and in yeast they may concentrate at the periphery. Young peroxisomes may have a more complex reticulated structure with internal membranes. Serial sectioning of mammalian liver or sebaceous glands, sources that have very active peroxisomal lipid metabolism, reveal that peroxisomes can be connected to each other by tubules, forming an extensive peroxisomal reticulum. Whether such tubules could also represent endoplasmic reticulum has been a contentious issue since the 1960s, although recent strong evidence in favor of this link has been provided. Besides a relationship to the endoplasmic reticulum, peroxisomes have been noted to be in close apposition to mitochondria and lipid bodies, and evidence has been put forward to support hypotheses of peroxisomal origins from each of these compartments.

The matrix is usually more electron dense than the surrounding cytoplasm. Peroxisomes of many organisms, from fungi to mammals (but not humans), contain a core of particularly dense protein within the matrix that is organized in a paracrystalline matrix. These can allow easy discrimination of peroxisomes from other structures. Cores can be cuboidal, plate-like, or more amorphous. The core can govern organellar shape. In the methylotroph *Hansenula polymorpha*, for example, peroxisomes are cuboidal, the membrane wrapping around the large core of alcohol oxidase (Fig. 1). The regular pattern of crystalloids represents a single protein, although others may penetrate the core in a more soluble state. The ground substance of the matrix usually appears uniform and granular, although areas of fibrillar structure have been described for mammalian tissue. The matrix, even disregarding the core, is not a uniform

mixture of proteins; as peroxisomes are gently lysed, some matrix proteins leak much more readily than others; the less soluble proteins are presumed to be bound to the membrane, to the core, or to other less apparent structural components.

As noted above, a hallmark of peroxisomes is the presence of oxidases (Fig. 2). Typical substrates include lipids, alcohols, purines, and amino acids. These enzymes are responsible not only for the disposition of the end products of metabolism but also to generate important molecules for signal transduction, intermediates in assimilatory pathways, or substrates for specialized functions in the same cells or for remote tissues of the organism. Besides oxidative reactions, peroxisomes catalyze steps in many other pathways. The packaging of enzymes within peroxisomes may serve two important functions. Segregation of peroxisomal oxidative enzymes with catalase, other peroxidases, or superoxide dismutase certainly protects the cytoplasm

from oxidative stress. (Interestingly, reactive oxygen species that escape from peroxisomes can perform useful functions under certain conditions.) The other result of sequestering peroxisomal enzymes may be to prevent ''metabolic interference''; their presence in the cytoplasm may initiate energetically wasteful futile cycles of metabolites. Thus, while the initial segregation of peroxisomal proteins may have been the result of an ancient microbial symbiosis, the host cells seem to have parlayed this relationship to optimal advantage.

Many peroxisomal enzymatic reactions are performed in other compartments as well. This is the case for β-oxidation of fatty acids (shared by the mitochondria in mammals), the glyoxylate cycle (shared by the cytoplasm in yeast), or sterol biosynthesis (shared by the endoplasmic reticulum in animals). In some cases, this is explained by a requirement of an enzymatic step in two distinct pathways that must be segregated from each other in two compartments to maximize flux. Often, specialization has occurred in the two compartments. For example, the oxidation of very long versus medium-length fatty acids is accommodated by peroxisomes and mitochondria, respectively, in mammalian tissues. In this case, two distinct sets of enzymes perform largely similar reactions in the two organelles. Often, however, gene products are dually localized (Table 1). Proteins that are colocalized to mitochondria and peroxisomes have the potential for an amino terminal mitochondrial-targeting signal, as well as a peroxisomal signal at the carboxy terminus. The mitochondrial signal may be absent in some molecules because of alternative splicing or initiation at an alternative translational start site. In several cases, however, the identical translation product is dually localized. A weak peroxisomal targeting signal (i.e. straying from the consensus sequence) is often but not always

Tab. 1 Some dually localized peroxisomal enzymes.[a]

Enzyme	*Species*	*Other location*	*Comments*
Epoxide hydrolase	Rat	Cytosol	PTS1 (SKI) inefficiently targeted?

Cu, Zn SOD	Mammals	Mitochondria /cytosol/lysosome?	Cryptic mitochondrial-targeting sequence

[a] Does not include peroxins known to shuttle from cytosol to peroxisomes.

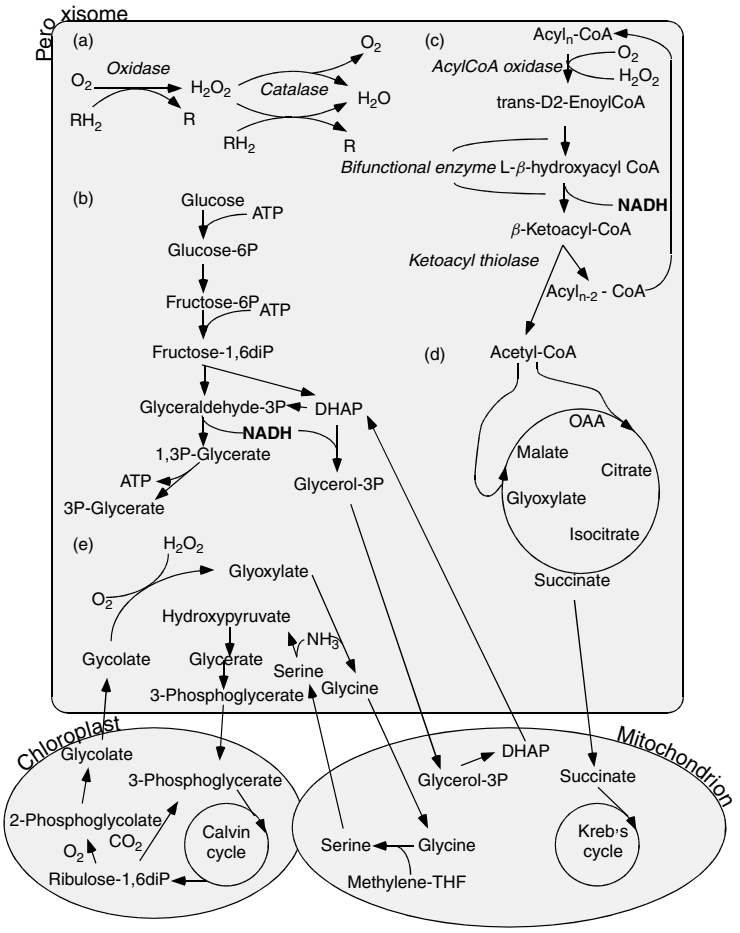

Fig. 2 Examples of peroxisome metabolic pathways. (a) The prototypic peroxisomal oxidase reaction and detoxification of hydrogen peroxide by catalase. (b) Glycolytic pathway in glycosomes. DHAP (dihydroxyacetone phosphate) is replenished from glycerol-3P in the mitochondria. 3P-glycerate exits the peroxisomes for further metabolism to pyruvate in the cytosol. (c) β-oxidation of fatty acids. (d) The glyoxylate cycle in plants, which allows the conversion of acetate to succinate, which can diffuse to mitochondria for gluconeogenesis ultimately to sucrose. (e) Contribution of peroxisomes in leaves to photorespiration, where 2-phosphoglycolate, the product of the rubisco oxygenase reaction in chloroplasts, will get converted, with the help of mitochondria, to 3-phosphoglycerate, the product of the rubisco carboxylase reaction.

found in these proteins, leading to ''mis-localization'' in the cytosol or preferential targeting to mitochondria. The balance of targeting can be shifted under different metabolic conditions, which can be caused by the induction or repression of receptors to the different targeting elements. It is a reasonable assumption that targeting of

these proteins is sometimes inefficient for important physiological reasons.

Peroxisomes have been most thoroughly studied in four systems: fungi (mainly yeasts), trypanosomatids, plants, and mammals. (Their functions and biogenesis in other vertebrates and in lower animals are relatively obscure.) Since the functions of peroxisomes have important and specific functions in these organisms, they will be discussed separately.

3 Specific Functions of Peroxisomes among Organisms

3.1 Peroxisomes in Fungi

Yeasts have played a major role in our understanding of peroxisomal function and biogenesis. It may be interesting for the reader to first consider a few major discoveries in the peroxisomal field using yeast systems in the context of other concurrent work.

The study of peroxisomes in fungi began as a search in the 1960s for a cheap source of food in animal husbandry and possibly for human use. Yeasts were identified by groups in Holland, Germany, and Japan that were able to grow on inexpensive and readily available carbon sources such as methanol or *n*-alkanes. When these strains were inspected by electron microscopy, investigators reported that microbodies were a prominent feature of the cytoplasm. Subsequent histocytochemistry and analysis of organellar fractions revealed that these structures contained oxidases and other enzymes that allowed the cells to assimilate the carbon source; they also contained catalase. Auspiciously, these observations were made shortly after the pioneering cell fractionation work of de Duve and Bauduin. The particles were therefore classified as peroxisomes. It soon became apparent that the size and number of these particles were controlled very tightly by growth substrate. Methylotrophs, for example, grown in glucose have only a few tiny peroxisomes, compared to the massive organelles in methanol medium. The plasticity of peroxisomes was further demonstrated in these yeasts when it was shown that the content of peroxisomes within a given species varied widely depending on the growth substrate; in contrast, a similar protein composition of the peroxisomal membrane demonstrated that these organelles were indeed related.

By this time, *Saccharomyces cerevisiae* had become a powerful model organism for genetic and biochemical approaches to biological problems. Although peroxisomes were discovered by Avers and Federman in *S. cerevisiae* in 1968, their existence in this model system was debated for many years. In normal glucose medium, they were difficult to detect by electron microscopy, no tools were available at this time for optical microscopy, and particulate catalase was attributed to vacuoles (lysosomes). Finally, in 1987 it was shown by Kunau, Veenhuis, and colleagues that growth on fatty acids caused peroxisomal proliferation such that peroxisomes were easily visible in the electron microscope. This observation, made at a time when the tools for molecular genetics were becoming very powerful in this system and the role of peroxisomes in human disease was apparent (see Sect. 6), generated much interest in the use of yeast for understanding peroxisomal assembly and function. Isolation of the organelles revealed that the β-oxidation pathway and several enzymes of the glyoxylate pathway

were contained within the peroxisome, allowing them to convert fatty acids to substrates for gluconeogensis and mitochondrial respiration. Not long after this, the genome sequence of *S. cerevisiae* was sequenced. Probing the genome for peroxisomal targeting sequences in the Gould laboratory revealed several proteins to be peroxisomal, including two components of the lysine biosynthetic pathway. Proteomic and genomic approaches have been since used for several other systems.

To complement ongoing work in *S. cerevisiae,* genetics were developed in methylotrophs (mainly *Pichia pastoris* and *H. polymorpha* and oleaginous yeasts (*Yarrowia lipolytica* and *Candida tropicalis*) as model systems to understand peroxisomal biogenesis. These systems have been crucial for the identification

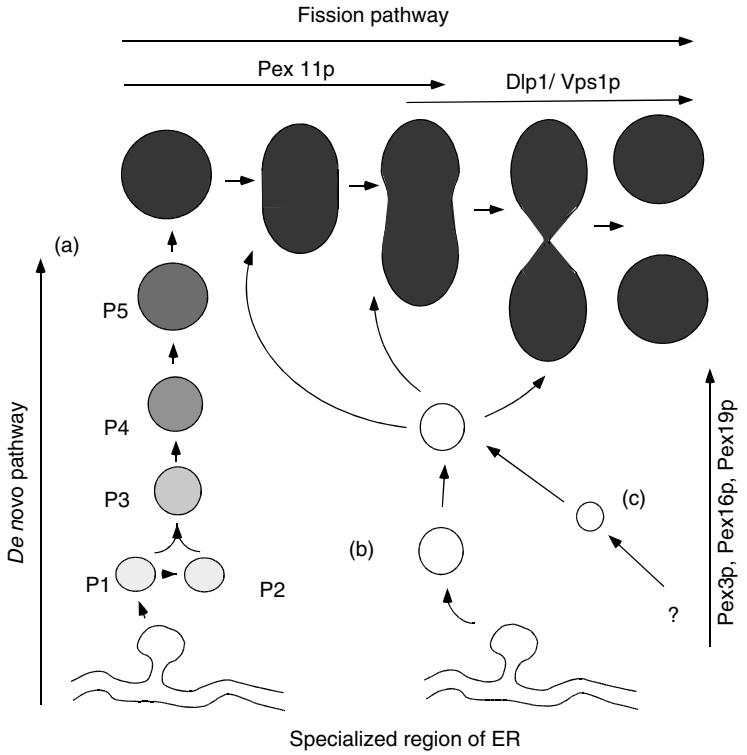

Fig. 3 Biogenesis of peroxisomes. Peroxisomes can divide by fission, top. Pex11p elongates the organelle and recruits the dynamin homolog Dlp1 (Vps1p in yeast) for organelle fission. (a) The *de novo* pathway in *Yarrowia lipolytica*, in which a series of discrete vesicular intermediates produce peroxisomes and also import subsets of matrix proteins (shading). (b) A hypothetical *de novo* pathway where vesicles bud from the endoplasmic reticulum (ER) and incorporate peroxins (Pex3p, which binds Pex19p and Pex16p) to target and assemble peroxisomal membrane proteins, which are required for matrix protein import. They fuse with mature peroxisomes. (c) Another hypothetical pathway in which vesicles are formed, but their source is unknown. This is considered as a possibility since the factors involved in classical budding from the ER seem not to be involved with peroxisomal assembly.

of genes and processes in the peroxisomal biosynthetic pathway. Genes so identified are termed *PEX*, and the corresponding proteins peroxins (Table 2). A discussion of their functions is provided in Sect. 4 below.

Yeasts, particularly *S. cerevisiae* and methylotrophs, have also been very important model systems for the study of peroxisomal degradation, since the switch from fatty acid or methanol to glucose normally results in rapid disappearance of peroxisomes. This process, termed *pexophagy*, takes two forms, micropexophagy and macropexophagy. Both are related to general autophagy, the process by which cells, when starved, digest portions of their cytoplasm to attempt to maintain viability. In macropexophagy, single peroxisomes are enwrapped in several layers of membrane (the source of which is unclear), which later fuse with elements of the vacuole, leading to digestion. Micropexophagy is analogous to general autophagy, where extensions of the vacuole surround groups of peroxisomes, directly leading to their digestion. Many genes have recently been identified that are required for pexophagy. Many of them overlap with autophagic genes. Interestingly, some of them also function in the cytosol-to-vacuole (cvt) pathway whereby precursors of at least two vacuolar proteins are normally synthesized in the cytosol and are delivered to the vacuole by a process resembling macropexophagy.

Molds and filamentous fungi also have peroxisomes that serve critical functions. In the filamentous fungus *Neurospora crassa*, peroxisomes contain the glyoxylate cycle and permit the cells to grow on acetate. More importantly, peroxisomes are essential for growth during hyphal growth of *N. crassa*. Mycelia formation is accompanied by the induction of Hex1p, which crystallizes in peroxisomes and buds from the organelle forming a structure termed a *Woronin body*. These particles are able to repair hyphae that become damaged by physically plugging holes in the cell membrane, thereby preventing the loss of cytoplasm and allowing other cell factors to seal the breach. New hyphae then can form adjacent to the initial event, expanding the organism.

Tab. 2 The localization and function of peroxins.

Peroxin	*Localization*	*Function*	*Comments*
Pex1p	Mainly cytosolic	Late in import; vesicle fusion?	AAA ATPase; associates with Pex6p
Pex2p	Peroxisomal membrane	Downstream of receptor docking	Zinc RING; associates with Pex10p
Pex3p	Peroxisomal membrane	Peroxisomal membrane biogenesis	Dock for Pex19p;
Pex4p	Cytosolic, peroxisomal membrane	Downstream of receptor docking	Binds to membrane via Pex22p; ubiquitin E2 ligase
Pex5p	Mainly cytosolic	PTS1 receptor	Binds cargo via TPR domains
Pex6p	Mainly cytosolic	Late in import; vesicle fusion?	Binds to membrane via Pex15p
Pex7p	Mainly cytosolic	PTS2 receptor	In mammals, can deliver cargo via Pex5p

Tab. 2 (*Continued*)

Peroxin	***Localization***	***Function***	***Comments***
Pex8p	Peroxisomal membrane	Links dock to RING proteins	Regulator of protein import?
Pex9p	Peroxisomal membrane	Protein import	Unique to *Y. lipolytica*
Pex10p	Peroxisomal membrane	Downstream of receptor docking	Zinc RING; binds to Pex2p, Pex10p, Pex5p
Pex11p	Peroxisomal membrane	Peroxisomal fission	Recruits dynamin-family members for fission
Pex12p	Peroxisomal membrane	Downstream of receptor docking	Zinc RING; binds to Pex10p and pex5p
Pex13p	Peroxisomal membrane	Docking	Binds to Pex14p and both PTS receptors
Pex14p	Peroxisomal membrane	Docking	Initial binding of Pex5p and Pex7p
Pex15p	Peroxisomal membrane	Protein import	Unique to *S. cerevisiae*; dock for Pex6p
Pex16p	Peroxisomal membrane	Peroxisomal membrane biogenesis	Binds to Pex19; absent in *S. cerevisiae*
Pex17p	Peroxisomal membrane	Docking	Binds to Pex14p; not in humans
Pex18p	Mainly cytosolic	PTS2 import	Binds to Pex7p
Pex19p	Mainly cytosolic	Peroxisomal membrane biogenesis	Docks on Pex3p; the likely PMP receptor
Pex20p	Mainly cytosolic	Thiolase import	Thiolase oligomerization; only in *Y. lipolytica*
Pex21p	Mainly cytosolic	PTS2 import	Only in *S. cerevisiae*
Pex22p	Peroxisomal membrane	Downstream of receptor docking	Docking of Pex4p
Pex23p	Peroxisomal membrane	Regulates peroxisomal size and number	
Pex24p	Peroxisomal membrane	Defective peroxisomal assembly	Mutants contain structures with a subset of peroxisomal proteins
Pex25p	Peroxisomal membrane	Regulates peroxisomal size and number	Binds to itself and Pex27p
Pex26p	Peroxisomal membrane	Protein import	Dock for Pex6p in humans
Pex27p	Peroxisomal membrane	Regulates peroxisomal size and number	Binds to itself and Pex25p
Pex28p	Peroxisomal membrane	Regulates peroxisomal size and number	Homologous to Pex24p
Pex29p	Peroxisomal membrane	Regulates peroxisomal size and number	Homologous to Pex24p
Pex30p	Peroxisomal membrane	Regulates peroxisomal size and number	Homologous to Pex23p; functions downstream of Pex28p and Pex29p
Pex31p	Peroxisomal membrane	Regulates peroxisomal size and number	Homologous to Pex23p; functions downstream of Pex28p and Pex29p
Pex32p	Peroxisomal membrane	Regulates peroxisomal size and number	Homologous to Pex23p; functions downstream of Pex28p and Pex29p

In penicillium molds, peroxisomes catalyze two critical steps in the biosynthesis of penicillin. Their importance is underscored by the finding that the amount of penicillin produced among species correlates with the number and size of their peroxisomes.

3.2 Peroxisomes in Trypanosomatids

Trypanosomatids are primitive flagellated protozoa that are responsible for widespread human suffering. The group contains trypanosomes and leishmania, the agents of African sleeping sickness, Chagas disease, and leishmaniasis.

These organisms contain glycosomes, organelles that contain enzymes of the Embden–Meyerhof pathway. The organelles are clearly in the peroxisome family since they contain catalase (in some species), their proteins usually terminate in peroxisomal targeting signals, and their assembly depends on peroxins, proteins that catalyze peroxisomal assembly.

Glycosomes contain the enzymes to catalyze the metabolism of glucose to 3-phosphoglycerate. This pathway does not result in net formation of ATP (this occurs at the pyruvate kinase step in the cytosol) but NADH is generated. NAD+ is reformed by the reduction of dihydroacetone (DHAP) phosphate to glycerol-3-phosphate. In itself this would result in loss of half the ATP from glucose (due to the loss of DHAP to glycerol), but the DHAP is regenerated from glycerol-3P in the mitochondria and circulated back to the glycosome, where it reenters the second half of the glycolytic pathway.

Trypanosomatids cycle between the mammalian bloodstream, insect gut, and salivary glands. When in the blood, trypanosomes are bathed in millimolar glucose. Mitochondrial respiration in the parasite is minimal and glycolytic enzymes are the major constituents of the glycosome. Once in the insect, however, amino acids are the major nutrients for the parasite (in its procyclic form). Subsequently, the composition of the glycosome changes; other pathways become more important for the organelle, and mitochondrial respiration and ATP generation are essential for survival.

Unlike yeast or isolated mammalian cells in culture, where peroxisomes are dispensable for maintenance and replication, trypanosomes die without glycosomes; organisms cannot be recovered from experiments in which PEX genes (i.e. those required for peroxisomal formation, see Sect. 6) are disrupted. It is thought that this reflects toxic effects of enzymes now in the cytosol, rather than a lack of glycosomal metabolism per se. Thus, when phosphoglycerate kinase, normally in glycosomes, is expressed in the cytosol, cells die. Interestingly, if the expression of PEX14 (required for peroxisomal protein import) is knocked down by RNAi technology, cells survived in the procyclic form, but only if glucose were not in the culture medium. Thus, the cytosolic mislocalization of glycolytic enzymes probably results in altered fluxes of intermediary metabolites in this compartment. While it was originally believed that the segregation of glycolytic enzymes within glycosomes was important for efficient channeling of pathway intermediates, the current thinking is that the compartmentation is essential to avoid interference of cytosolic metabolism by phosphorylated sugars from the glycosome. The precise mechanism of such toxicity remains to be elucidated.

Similar to mammalian peroxisomes (see below), glycosomes catalyze the biosynthesis of ether-linked phospholipids. The major surface glycosylphosphatidylinositol-linked protein of Leishmania, lipophosphoglycan, is bonded to the membrane via an ether- (instead of the normal ester-) phospholipid, a product of the glycosome. This surface molecule is not essential for life but is necessary for survival of the parasite within macrophages, which must occur for infection of mammals.

Finally, while peroxisomes in other cell types are well known to catabolize purines, glycosomes contain enzymes to salvage purines from the environment. This is an essential function since trypanosomes cannot synthesize them *de novo*. Both hypoxanthine guanine phosphoribosyl transferase and xanthine phosphoribosyl transferase contain peroxisomal targeting signals and are localized in glycosomes.

Recent analysis suggests that some glycosomal enzymes are of plant origin; similarities exist between algal and glycosomal forms. These include enzymes of glycolysis as well as the pentose-phosphate shunt and even the Calvin cycle! While this could indicate that glycosomes (and perhaps peroxisomes in other organisms) originated from an algal endosymbiont, it is also possible that the plant genes were acquired through lateral transfer after a phagocytic event.

3.3 Peroxisomes in Plants

Peroxisomes in higher plants are essential for seed germination and important in several metabolic pathways in the mature plant, including the synthesis of plant hormones and elucidation of signaling molecules. The development of molecular genetics in *Arabidopsis thaliana* has been the key to identifying many of these functions.

In oilseeds, energy is stored principally as triglycerides. Germination requires the conversion of these lipids to sugar, a process that requires fatty acid oxidation and the glyoxylate pathway. Fatty acids are metabolized to acetyl-CoA by β-oxidation, and the acetate is subsequently converted to succinate through the glyoxylate cycle. Both of these processes occur in an organelle termed the *glyoxysome*, a specialized type of peroxisome. During germination and leaf development, these organelles convert into leaf peroxisomes, as a specific subset of proteins is induced and imported into the organelles. That leaf peroxisomes develop from glyoxysomes and not from a separate source was shown by double immunogold electron microscopy using probes against enzymes in both pathways. In senescent plant tissues, backwards conversion into glyoxysomes occurs.

Leaf peroxisomes are central in photorespiration. In this process, the CO_2-fixing enzyme within plastids, ribulose-5-phosphate carboxylase/oxidase (Rubisco), accepts O_2 instead of CO_2, resulting in the formation of phosphoglycolate and phosphoglycerate (instead of two molecules of phosphoglycerate). Phosphoglycolate is dephosphorylated and shuttled into peroxisomes. Peroxisomes convert glycolate into glycine, which then can be transformed into serine within mitochondria, with a loss of CO_2. Serine shuttles back into peroxisomes and is converted there into phosphoglycerate, which can enter the plastid to complete the cycle. On balance, photorespiration appears wasteful for plants since it results in a loss of about 25% of fixed carbon with no gain in energy. However, it appears useful under conditions of low tissue CO_2 and

may be important for efficient utilization of nitrogen.

Plant peroxisomes are also important in hormone production and signal transduction. The hormone indole-3-acetic acid is generated in peroxisomes from indole-3-butyric acid. Similarly, the final step in the biosynthesis of jasmonate occurs in peroxisomes. Nitric oxide synthase, responsible for production of NO, has also been shown recently to be peroxisomal. Both hydrogen peroxide and superoxide, which can act as second messengers relaying information about the redox state of the cytoplasm, are generated within peroxisomes. Conversely, peroxisomal catalase has been shown to be essential for protection of the plant from oxidizing toxins such as paraquat and ozone.

Finally, there is evidence that peroxisomes play key roles in morphogenesis beyond their requirement for germination. The development of normal floral morphology can be severely altered and inhibited in an *aim1* mutant strain; *AIM1* appears to encode a peroxisomal fatty acid oxidation enzyme. Light-stimulated morphogenesis is also affected by peroxisomes. This pathway is rendered constitutive in a *det1* mutant; *DET1* encodes a DNA repressor. However, the effects of *det1* can be suppressed by a dominant mutant in *TED3*, which itself encodes Pex2p, a peroxisomal integral membrane protein that is a member of the protein import complex. While the details of the *DET1-TED3* interaction remain to be worked out, it is another example of a role of peroxisomes in development and signaling.

3.4 Peroxisomes in Mammals

A principal role of mammalian peroxisomes is the β-oxidation of long-chain ($C_{12}-C_{18}$) and very long chain fatty acids ($C_{20}-C_{26}$). In yeast, all fatty acid β-oxidation occurs in peroxisomes and it is the major locus for this activity in plants. In mammals, the peroxisomal pathway prefers the long and very long chains. In the organelle, they are metabolized to medium chain fatty acids, which are then shuttled as carnitine conjugates to the mitochondria for further oxidation. Peroxisomal enzymes of this pathway are distinct from the mitochondrial forms and contain peroxisomal targeting signals. The reactions in the pathway are similar in the two organelles except for the initial step. In the mitochondria, acyl-CoAs are converted to enoyl-CoAs by an NADH dehydrogenase, thereby generating reducing equivalents. In peroxisomes, the step is catalyzed by an oxidase, which generates hydrogen peroxide from molecular oxygen. The peroxide is then destroyed by catalase. The enzymology of subsequent steps is similar in the two organelles.

Peroxisomes are also critical in metabolizing branched chain fatty acids. Two-branched fatty acids, such as phytanic acid, a product of chlorophyll breakdown and an abundant product in injested plants, cannot utilize the β-oxidation pathway directly and must be first metabolized by a single round of α-oxidation, using peroxisomal enzymes to convert phytanic to pristanic acid, which can then be metabolized by the β-oxidation pathway.

Induction of the peroxisomal fatty acid oxidation pathway is catalyzed by the α-isoform of peroxisome proliferator–activator receptor (PPARα). The PPARs are a family of nuclear receptors that form heterodimers with retinoid X receptor (RXR) and control transcription of several metabolic pathways. PPARα is expressed mainly to liver and to a lesser

extent to heart and skeletal muscle. After fasting, fatty acids released by adipose tissue bind to the receptor, inducing peroxisome and mitochondrial proliferation and fatty acid oxidation, thus providing ketone bodies to the periphery as an energy source. While the induction of metabolic enzymes by PPARα is understood in some detail, the way in which organelle proliferation per se is induced is less clear.

Reactions similar to those of peroxisomal β-oxidation catalyze chain shortening of C_{27}-sterols to form bile acids within peroxisomes.

Peroxisomes also catalyze the initial steps in the synthesis of ether-linked phospholipids. Compared to the better-known ester-linked glycerolipids, there is an ether (in plasmanyl phospholipids such as platelet activating factor) or ether-vinyl linkage (in plasmalogens) at the sn-1 position of the glycerol backbone. Platelet activating factor is a potent cytokine that promotes inflammation through PAF receptors on the cell surface. Plasmalogens are at high levels in nervous system tissue and comprise most of the phospholipids in myelin. Although the precise physiological roles of plasmalogens are not fully understood, they are probably important for maintaining lipid fluidity and contributing to efficient endocytosis and other events of membrane dynamics. Since the sn-2 position of plasmalogens is often polyunsaturated fatty acids, they are targets of PLA_2 enzymes and may generate the bulk of arachidonic and docosahexaenoic acids, sources for ecosinoids such as prostaglandins, extremely potent second messengers.

Peroxisomes contain several enzymes in the cholesterol biosynthetic pathway. However, none of these enzymes are uniquely found in this compartment, and the amount of cholesterol biosynthesis in fibroblasts is not much decreased in the absence of the organelle (i.e. from patients with peroxisomal biogenesis disorders). Thus, the physiological significance of peroxisomal cholesterol biosynthesis is not clear.

There are several known flavin oxidases in mammalian peroxisomes besides the acyl-CoA oxidase that functions in the β-oxidation pathway. L-α-hydroxyacid oxidase is active against small molecules such as glycolate, lactate, and a few L-amino acids. Distinct from this enzyme is D-amino acid oxidase, which has a broad specificity for D-amino acids. Since intermediary mammalian metabolism utilizes L-amino acids, the function of this oxidase remains a mystery. One hypothesis is that it is there to metabolize bacterial products that find their way to the bloodstream. Another idea is that it metabolizes glycine or D-serine in the nervous system, thus possibly regulating the action of these important neurotransmitters.

Uric acid oxidase (uricase) is the initial enzyme in the breakdown of uric acid in many mammalian species. Rodent peroxisomes are distinguished by a crystalloid core in which uricase and other proteins are localized. The enzyme is absent in humans and anthropoid apes, whose peroxisomes lack cores. Finally, peroxisomal oxidases metabolize polyamines, which are important for stability of nucleic acids and for a variety of growth processes, and pipecolic acid, a degradation product of lysine.

Mammalian peroxisomes contain alanine: glyoxylate aminotransferase, which catalyzes the conversion of glyoxylate to glycine, thereby detoxifying cells of glyoxylate. Otherwise, glyoxylate is oxidized to oxalic acid, which is insoluble and crystallizes in the kidney leading to serious disease, further discussed in Sect. 6.

4
Biogenesis of Peroxisomes

4.1
Origin of the Peroxisome

It is not clear whether the first eukaryotic peroxisome was the result of internalization of a prokaryotic ancestor, as is the case for mitochondria, or whether eukaryotes were entirely responsible for biosynthesis for these organelles. Mitochondria contain a genome and machinery for DNA replication and protein synthesis that can be traced back to prokaryotic ancestors. Peroxisomes have no genome, and there is no apparent homology between groups of structural or enzymatic components of these organelles and prokaryotic counterparts, except for the homology between glycosomal and algal proteins noted earlier. There is no evidence, such as skewed codon usage, for ancient transfer of hypothetical genetic elements between peroxisome and nucleus. However, such differences might have existed long ago and have been erased over hundreds of millions of years of evolution. Thus far, there is no compelling evidence to support or refute the endosymbionic origin of peroxisomes.

4.2
Peroxisome Fission

Similar to mitochondria, peroxisomes can divide by fission (Fig. 3). Pex11p is considered to be the major fission factor that acts from the peroxisomal membrane, since its absence results in fewer peroxisomes, some of which are much larger than in wild type; expression of Pex11p in a null background causes the fission of the large organelles. Overexpression of Pex11p leads to an increased number of small organelles. Pex11p can self-associate in oligomers, and there is evidence that this behavior regulates its action. The carboxy terminus of Pex11p can bind coatomer, which is involved in vesicle formation and thus might promote fission, but the physiological significance of this observation has been questioned. Recently several other peroxins, Pex23p, Pex25p, and Pex27p through Pex32p have been identified that also regulate peroxisomal number and size. Many of these interact with each other, and epistasis analysis has demonstrated some order of events; for example, Pex31p and Pex32p function after Pex28p and Pex29p. Some of these factors may be working in a *de novo* pathway rather than in peroxisomal fission (see below). The number of proteins that regulate peroxisomal size and number suggest a complex mechanism for these processes.

Pex11p recruits Dlp1 (Vps1p in yeast), a member of the dynamin family, to peroxisomes. Dynamin has been shown to promote scission of vesicles from the plasma membrane during endocytosis. Whether dynamins themselves induce membrane fission or act as switches for other motor proteins is under active investigation. Regardless, this family of proteins promotes both mitochondrial and peroxisomal division. If expression of Dlp1 is silenced or dominant-negative alleles are used, long tubulated peroxisomes are formed, and these structures are even more pronounced if Pex11p is overexpressed. A fluorescently tagged Dlp1 catalytically inactive mutant shows a striped pattern on these tubules, which alternates with the Pex11p pattern. Although Pex11p is necessary for recruitment of Dlp1p, direct association of these two proteins cannot yet be demonstrated, suggesting that the interaction is indirect.

While yeast has 1 Pex11p, humans have three isoforms. Pex11α is induced by PPAR while Pex11β and Pex11γ are constitutive. In mice, 11β is essential for peroxisomal function (see Sect. 6).

4.3 The Origin and Assembly of the Peroxisomal Membrane

Besides peroxisomal fission, *de novo* biogenesis of peroxisomes also occurs. One line of evidence for this alternative pathway is the formation of peroxisomes in cells apparently lacking any. For example, a pex16 mutant fibroblast line has no visible peroxisomes or remnant peroxisomal membranes. If wild-type PEX16 is then introduced into these cells, peroxisomes appear. A second line of evidence is that continuities have been shown between membranes of the endoplasmic reticulum (ER) and peroxisome-related structures. Finally, mutants in the secretory pathway mislocalize peroxisomal proteins. While all these data point to the ER as the source of peroxisomes, such a pathway would have novel elements: peroxisomal matrix proteins do not enter the lumen of the ER *en route* to peroxisomes. The Sec61 complex in the ER membrane, through which secreted proteins and most membrane proteins destined for the exocytic pathway pass, is not involved with peroxisomal biogenesis. Neither COP1 nor COPII is required for peroxisomal assembly. With two probable exceptions in the yeast *Y. lipolytica* (Pex2p and Pex16p), no peroxisomal proteins are glycosylated. Experiments in *Y. lipolytica* have demonstrated that a discrete series of vesicular intermediates derived from the ER comprises the *de novo* pathway in that organism. Such a pathway has not yet been shown in other organisms, however. Regardless of the details, it is clear that the ER plays a role in *de novo* peroxisomal assembly in some way.

Three proteins have been shown to be important in the delivery of peroxisomal membrane proteins (PMPs) to nascent organelles: Pex19p, Pex3p, and in some species, Pex16p. Pex19p is a mainly cytosolic protein that binds to most PMPs. While there was much debate on whether Pex19p served as the PMP receptor to guide newly synthesized PMPs to the membrane, or instead served as a chaperone for integration once the protein was targeted, the consensus is now that it indeed binds to targeting elements on PMPs. A critical experiment to this end demonstrated that if Pex19p was intentionally mistargeted to the nucleus, many PMPs arrived there as well. Pex19p can bind to Pex3p, an integral membrane protein, which probably serves as a docking element for Pex19p-PMP complexes. In mammalian cells, the membrane protein Pex16p is also involved with PMP targeting and may stabilize Pex3p-Pex19p interactions. In the absence of any one of these three peroxins, peroxisomes are absent, and membranous remnants are difficult to find.

Unlike PTS1, which is very easy to recognize (see below), there is no motif (termed *mPTS*) easily recognizable on PMPs. Many PMPs have been analyzed for targeting information. In general, the mPTS consists of a transmembrane element and sequences adjacent. The matrix-facing sequences contain net basic charge and the cytosol-facing adjacent sequence often predicts an amphipathic helix. Several PMPs contain two mPTSs that can function independently of each other. Their role may be to increase the efficiency of targeting (for example, by binding to multiple Pex19p molecules) or to target the cargo to different subpopulations of peroxisomes. The extent to which the Pex(3,16,19)p system

acts to target PMPs to a preperoxisomal compartment (to establish the machinery for protein import into the matrix) versus to mature peroxisomes is not known but may depend on the fraction of organelles being generated by the fission versus *de novo* pathway.

To summarize, the weight of the evidence supports the existence of an ER-based *de novo* pathway for peroxisomal generation. Many details of this pathway, however, are not clear. The ER does not appear to function as it does in the classical exocytic pathway. There is no consensus on whether peroxisomes, near maturity, bud from the ER or whether a series of small vesicles are involved. Different mechanisms may work in different cell types. If a specialized region of the ER is involved, the nature of this compartment has not been elucidated. The next few years are likely to see resolution to this fascinating problem.

4.4 Import of Proteins into Peroxisomes

The last 15 years has seen remarkable progress toward a molecular understanding of peroxisomal import of proteins. However, some aspects of the basic mechanism remain unresolved.

Peroxisomal matrix proteins are synthesized in the cytoplasm. Nearly all of them contain a short targeting motif at their extreme carboxy terminus termed *PTS1* (*peroxisomal targeting signal 1*). The prototypic sequence of the PTS1 is SKL (serine-lysine-leucine), although many variations of this can be found, some of which are favored in various cell types. Several matrix proteins are targeted instead by a non-apeptidyl PTS2 sequence at or near their amino termini. This targeting signal is less conserved than PTS1 and consists of –(R/K)(L/V/I/Q)XX(L/V/I/H/Q)(L/S/G/A/K)X(H/Q)(L/A/F)–. In some systems, the amino terminus containing PTS2 is proteolytically removed during import. A few peroxisomal proteins have both PTS1 and PTS2 signals, and a few others have neither (see below).

Unlike classical protein import pathways across mitochondrial or ER membranes where unfolded proteins enter the import apparatus, peroxisomal cargo folds and assembles into oligomers before translocation. This has been demonstrated in several systems by coexpressing protein subunits that are lacking or containing PTS sequences (in which subunits without the signal are imported by a ''piggyback'' mechanism), as well as in pulse-chase experiments. The capacity for peroxisomes to import large molecules is also demonstrated by their ability to import colloidal gold particles conjugated with a peroxisomal targeting signal. Proteins, with few exceptions, enter peroxisomes as holoenzymes. The sole exception so far to this rule is alcohol oxidase, a 600-kDa homooctamer in methylotrophic yeasts, which is imported as monomers and assembles within the matrix of yeast peroxisomes. Whether this protein is simply too large to cross the peroxisomal membrane, or must assemble internally for other reasons, is not known.

Cytosolic chaperones play important roles in various protein import pathways. In many systems, proteins in the dnaK (Hsp70) and dnaJ families (initially identified in *Escherichia coli* in DNA replication and later as heat-shock proteins, Hsp) interact to maintain cargo in an unfolded state and protect them from aggregation before they encounter an import apparatus. Hsp70 and Djp1 (a dnaJ protein) have been shown to be important for peroxisomal import as well. However, instead of

keeping peroxisomal cargo unfolded, they act either in the folding of cargo or in keeping the PTS accessible to receptor.

The receptors to which the PTS1 and PTS2 bind are Pex5p and Pex7p, respectively (Fig. 4). The structure of Pex5p in complex with PTS1 has been solved. The carboxyl half of the molecule consists of six tetratricopeptide repeats, which form a sandwich around the PTS1 peptide. As mentioned earlier, a few matrix proteins contain no recognizable PTSs. However, their import depends on Pex5p, and they probably bind to this molecule outside of the normal PTS1-binding area.

In yeast, import of PTS2 cargo by Pex7p occurs independently of Pex5p. However, in mammals import requires Pex5p, an unexpected observation. Two forms of Pex5p are synthesized, one with a 37-amino acid extension produced by alternate splicing of the RNA. The Pex5L (long) form can bind Pex7p through the extension, and the extension is required for Pex7p-mediated PTS2 import. In yeast systems, there are accessory proteins in PTS2 import that may replace the function of the Pex5L extension in PTS2 import.

Since most peroxisomal cargos are oligomers, and Pex5p itself form tetramers, it is easy to imagine that large complexes may develop between receptor and cargo. According to the preimplex model of Gould, the formation of these complexes on the peroxisomal surface may be an important intermediate in import.

Once receptor binds to cargo, the complex docks on the peroxisomal surface. The minimal docking structure consists of Pex14p, Pex13p, and Pex17p, all membrane proteins. Binding studies indicate that Pex14p can self-associate and probably dimerizes in the membrane. In most systems, it behaves as a transmembrane protein and probably provides the first contact with the cargo-bound receptor. Cargo-bound Pex5p preferentially associates with Pex14p, probably because the cargo unmasks the Pex14p binding site on the amino terminal segment of Pex5p. Pex14p in turn associates with Pex13p and Pex17p. Pex17p is a peripheral element (facing the cytoplasm) and is nonessential to import in some systems. Pex13p, an integral membrane protein, binds to Pex7p in yeast through its amino terminus, and binds to Pex5p and Pex14p at its carboxy terminus. Both termini face the cytoplasm.

What happens after binding of receptor-cargo to the docking complex is not clearly understood yet. Several proteins act downstream of docking, shown by epistasis experiments; docking is not affected if they are eliminated. The docking complex can associate with another complex of three proteins, Pex2p, Pex10p, and Pex12p. All of these are essential for import. Each member of this trio contains a zinc RING motif facing the cytoplasm. Recent data indicates that the link between the docking and RING complexes is Pex8p, a peripheral membrane element that faces the matrix. However, Pex8p is present at lower concentrations than the other proteins of the two complexes, so that the linkage may be regulated rather than constitutive.

There has been much debate over whether the cytosolic receptors enter the matrix to drop off cargo (the simple vs extended shuttle model). The weight of the evidence favors the extended model whereby Pex5p and Pex7p release their cargo in the matrix. A fraction of these molecules are sometimes found in the matrix, and defective alleles in downstream peroxins often lead to the accumulation of receptors in that compartment. Pex5p has been shown to become protease-protected (i.e. protected by the membrane) during its

import cycle. Furthermore, Pex8p, which is not exposed to the cytoplasm face, can bind Pex5p. Finally, Pex5p with an added PTS2 extension that is normally cleaved in the matrix is similarly cleaved during import. Data from a mammalian *in vitro* import model suggests that Pex5p remains associated with the membrane at every step of its cycling reaction, so the protein may not necessarily entirely enter the matrix, but only drop off its cargo at the internal surface.

Two other membrane protein complexes function downstream of import: one containing two ATPases, and the other an E2 ubiquitin ligase.

Pex1p (altered *PEX1* alleles commonly cause human peroxisomal diseases, see Sect. 6) and Pex6p contain Walker ATPase domains and associate with each other. Although largely cytosolic, a fraction of each associates with the peroxisomal membrane by binding to integral membrane proteins: Pex15p in yeast and Pex26p in mammals. The ATPase function on both is critical to the import cycle, but its precise role is controversial. According to the preimplex model, Pex1p and Pex6p may serve to disassemble large receptor–cargo complexes once they have bound to the docking apparatus, and allow the import of single units. Another idea is that they are essential for the export of receptor after release of cargo in the matrix. In support of this hypothesis, it has been shown that export, but not import, of proteins is an ATPase-requiring step. Finally, in the yeast *Y. lipolytica*, Pex1p and Pex6p appear to be involved with fusion of preperoxisomal vesicles. It is very difficult to reconcile a role for these proteins in vesicle fusion versus protein import or export unless the import cycle is not strictly the movement of proteins through a proteinaceous gate in the membrane but instead involves membrane dynamics to an extent not appreciated or understood at present.

The last complex that participates in the import cycle contains Pex4p and Pex22p. Pex4p is a peripheral protein that is anchored to the bilayer by Pex22p. The dimer can bind to the RING complex through Pex4p–Pex10p interactions, linking them indirectly to the docking complex. Epistasis experiments place them after the Pex1p–Pex6p complex, however, and they are assumed to participate in Pex5p recycling to the cytosol.

Pex4p is an E2 ubiquitin ligase. Protein ubiquitination (ubiquitin is a small peptide) is widely known to be a tagging mechanism for proteins destined for degradation in the proteosome. It is also known, however, to be involved in other protein trafficking pathways, for example, recycling of plasma membrane receptors. How ubiquitination relates to the importance of Pex4p for protein import into peroxisomes has been a riddle since its sequence was determined. Very recently it was shown that Pex5p is ubiquitinated by Pex4p, and that this reaction prevents Pex5p from polyubiquitination and degradation. E2 ligases usually transfer ubiquitin moieties through E3 ligases. Pex10p is required for Pex5p-mediated monoubiquitylation, and thus Pex10p is a good candidate for the E3 enzyme. These data explain older experiments in which peroxin mutants led to instability of Pex5p. Pex4p may serve to regulate the concentration of Pex5p to peroxisomal need: The receptor is kept at low levels with relatively inactive peroxisomes, and increases in concentration (due to stabilization by monoubiquitylation) when peroxisomal import is upregulated.

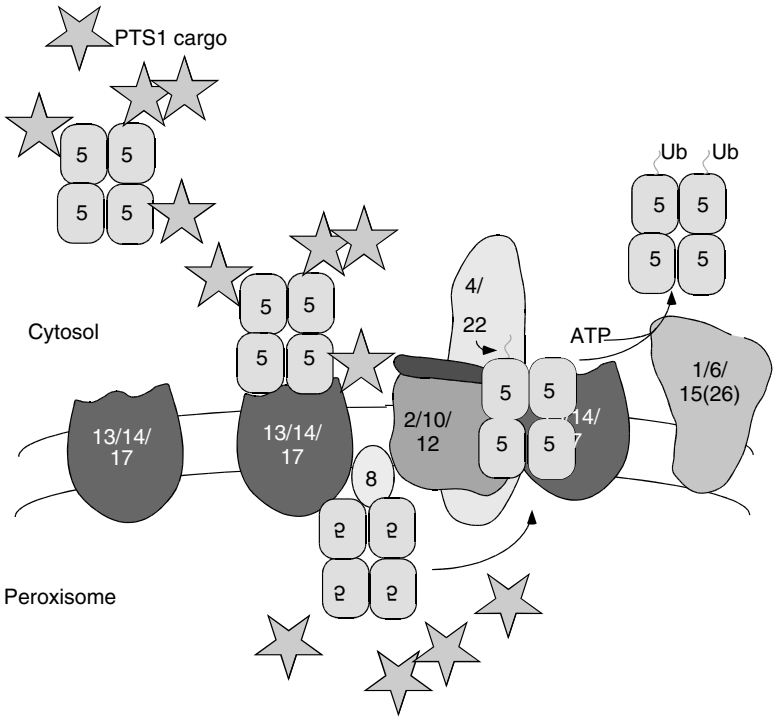

Fig. 4 Protein translocation across the peroxisomal membrane. Pex5p ("5" in the figure) with PTS1 cargo (stars) docks to the Pex13p–Pex14p–Pex17p complex. Subsequent steps are less clear, but require the other peroxins shown. Cargo is most likely released in the matrix. The Pex2–Pex10p–Pex12p complex contain interacting RING motifs, shown in dark red; it is not clear whether they are required for import or recycling of receptor. Pex8p links these two complexes as shown. Pex4p is an E2 ubiquitin ligase that monoubiquitinates Pex5p, preventing polyubiquitination and degradation by the proteosome. The ATPases Pex1p and Pex6p are shown promoting the export of receptor, although it is possible that they function earlier in the pathway, such as in the dissociation of receptor and cargo. (See color plate p. xxxiv).

5 Peroxisomal Motility

Observations of peroxisomes in living cells was made possible by the use of fluorescent tags, such as green fluorescent protein (GFP)-PTS1. Experiments in mammalian cultured cells revealed that peroxisomes fell into two classes; most moved randomly with no net spacial translation, while 10 to 15% move rapidly and directionally. Since inhibitors of microtubule assembly, but not inhibitors of actin assembly, inhibited this movement, it was concluded that peroxisomes can move on microtubules.

Particles that move on microtubules can utilize either dynein or kinesin-based motors. Both systems utilize ATP hydrolysis for movement, and peroxisomes have been shown *in vitro* to move on microtubules in an ATP-dependent fashion. While neither dynein nor kinesin has been shown to bind to peroxisomes, a dominant-negative fragment of dynactin, a dynein-accessory

protein, inhibits peroxisomal movement. Interestingly, purified peroxisomes can bind directly to purified microtubules, suggesting that the peroxisomal membrane contains specific microtubule-binding elements. This is supported by the finding that protease-treatment of intact peroxisomes results in the loss of microtubule binding. The factor responsible, however, has not yet been identified.

In contrast to their behavior in animal cells, peroxisomes in plant and yeast cells utilize actin-based motors for movement. In yeast, Myo2p is necessary for movement on actin cables, and this movement is essential for segregation of peroxisomes into buds during division. Actin is also important for the movement of plant peroxisomes; drugs that block actin also inhibit movement of peroxisomes.

Why move peroxisomes along microtubules? Peroxisomes display a uniform distribution in animal cells. In contrast, they can be in close proximity to the endoplasmic reticulum and to lipid bodies, which may reflect their origin or need for lipid substrates, respectively. Microtubules may be responsible for transporting peroxisomes to or from these sites. In some tissues, peroxisomes show a polar distribution, such as their appearance at the basolateral pole of proximal tubular cells of the kidney, and microtubules may be required to maintain that polarity. These filaments appear not to be important for segregation in animal cells during cytokinesis, since this process seems to be random.

6 Peroxisomal Diseases

The vital role of peroxisomes in early plant development has been described earlier (Sect. 3). In contrast, mammals can give birth to offspring that lack peroxisomes, but they are severely deficient in many organ systems and do not survive long afterwards. Human peroxisomal diseases are subdivided into those with a single enzyme deficiency, and the peroxisome biogenesis disorders (PBDs) with defects in *PEX* genes.

6.1 Single Enzyme Disorders

There are several disorders caused by defects in single peroxisomal matrix proteins. These range from the relatively benign (catalasemia) to the more serious (X-linked adrenoleukodystrophy (XALD)). XALD is characterized by an accumulation of very long chain fatty acids caused by defects in a peroxisomal membrane protein that probably encodes a subunit of the fatty acid transporter. Depending on the allele, patients may be stricken in adulthood with a disease that is degenerative over several generations, or present with the disease in childhood and show rapid disease progression. Symptoms are neurological (including severe mental retardation in severe cases) as well as endocrine, particularly involving adrenal insufficiency.

A peroxisomal single enzyme deficiency with an interesting mechanism is hyperoxaluria type I; afflicted patients generate extensive renal oxalate stones resulting in extensive kidney damage. The disease is caused by point mutations in the peroxisomal enzyme alanine glyoxylate aminotransferase (AGT), which normally converts glyoxylate to glycine in peroxisomes. Wild-type AGT forms homodimers in the cytosol and is targeted to peroxisomes by a PTS1. In some patients, the enzyme is inactive or forms

aggregates. In other patients, however, two mutations in AGT prevent cytosolic dimerization and concomitantly convert a cryptic mitochondrial-targeting signal to an active one. These mutations in combination cause AGT to mistarget to mitochondria. In this compartment, glyoxylate is not metabolized. Instead, it becomes oxidized to the more insoluble oxalate, causing hyperoxaluria and calcium oxalate stones.

6.2 Peroxisome Biogenesis Disorders

In 1964, a hereditary metabolic disease in infants was described by Zellweger and colleagues, characterized by severe hypotonia, craniofacial abnormalities, hepatomegaly, renal cysts, and mental retardation. Children severely affected lived only weeks or a few months. In 1973, Goldfischer and coworkers made the observation that cells from these patients lacked peroxisomes. Since then it has become clear that peroxisomal biogenesis disorders comprise a spectrum of diseases that range from Zellweger syndrome as the most severe, through neonatal adrenoleukodystrophy in intermediate severity, to infantile Refsum's disease as the mildest form. As it became appreciated that all of these diseases shared a lack of peroxisomes, complementation studies were performed by cell fusion assays to determine the number of genes involved. Fibroblasts from patients fell into 12 (now 14) complementation groups. Identification of the genes responsible was greatly facilitated by sequence information of yeast *PEX* genes. The severity of symptoms (and the assignment to the particular PBD) was found to be more a function of the degree of inactivation of the PEX gene product rather than of specific *PEX* genes. Mutations in PEX6 are responsible for nearly 70% of all PBDs.

Severely affected patients have large increases in concentrations of very long chain fatty acids and of bile acid intermediates, consistent with a decrease in peroxisomal fatty acid β-oxidation pathways (Table 3). They show deficiencies in plasmalogens and the enzymes of ether lipid biogenesis associated with peroxisomes. Defective ether lipid synthesis is thought to be responsible for defects in neuronal migration and the establishment

Tab. 3 Some biochemical abnormalities in Zellweger spectrum PBDs.[a]

Substrate or Enzyme	*Change*	*Comment*
Very long chain fatty acids	Greatly elevated	Defect in β-oxidation
Bile acid intermediates	Greatly elevated	Defect in β-oxidation
Pristanic acid	Elevated	Defect in β-oxidation
Phytanic acid	Elevated	Defect in α-oxidation
Plasmalogens (products of peroxisomal metabolism)	Greatly decreased	Defect in ether lipid biogenesis
DHAP aminotransferase	Greatly decreased	Mislocalized
Acyl-CoA oxidase	Greatly decreased	Mislocalized and degraded
Catalase	Mislocalized	Active in cytosol

of white matter during the development of the central nervous system.

Another disease, rhizomelic chondrodysplasia punctata (RCDP) has several common features to Zellweger syndrome, particularly altered bone growth (punctate calcifications of cartilage and shortening of the humerus and femur) as well as hypotonia and neurological symptoms. Cataracts are common. Depending on allele and with proper support, patients with RCDP can live for several decades. The main cause of the disease appears to be poor synthesis of ether lipids, either from a defect in *PEX7* leading to a specific PTS2 import defect, or the loss of dihydroxyacetonephosphate acyltransferase, a key peroxisomal enzyme in the ether lipid biosynthetic and a PTS2 substrate. RCDP illustrates the importance of ether lipids for normal physiology.

6.3 Mouse Models for PBDs

Gene disruptions in mice have been extraordinarily helpful in understanding human disease. Thus far knockouts have been generated in PEX2, PEX5, PEX13, PEX11α, and PEX11β. Mice homozygous for disruptions in PEX2, PEX5, and PEX13 die shortly after birth and exhibit many symptoms similar to Zellweger syndrome: low birth weight, lack of neuronal migration, poor feeding, and hypotonia. Similar to humans they lack viable peroxisomes but contain peroxisomal ghosts. Thus, they appear to be good models for human PBDs. Interestingly, in PEX5 $-/-$cells, the defect in neuronal migration (certainly involved with the mental retardation in children) is not corrected by reintroducing brain-specific PEX5 expression; the defect is still seen in animals not expressing the gene product in liver. Only by expressing PEX5 in liver and in brain is this neurological defect corrected.

As indicated earlier, PEX11 has three isoforms in humans, α, β and γ; knockouts have been made in the α- and β-isoforms. Unexpectedly, there was no phenotype in the mice lacking PEX11α, the form that is induced by PPARα. Even more surprising was the finding that peroxisomal number increased in response to PPARα agents, demonstrating that Pex11α is not necessary for peroxisomal induction by this transcription factor. In contrast, peroxisomes were less abundant in mice in which PEX11β, a constitutive and widely expressed form, was disrupted, and the animals displayed a Zellweger-like phenotype. The concentration of peroxisomal products and intermediates were only mildly altered; the reason for the severe phenotype in these animals is not yet clear.

The mouse disruption has also helped settle a controversy on the importance of peroxisomal cholesterol biosynthesis. Many enzymes in isoprenoid biosynthesis (shared in the cholesterol pathway) are localized in peroxisomes and their physiological significance has been uncertain. Mice lacking peroxisomes have only minor (if any) alterations in overall sterol biosynthesis; there may be a minor difference in liver biosynthesis. Thus, the role of peroxisomes in this pathway remains uncertain.

Keywords

Chemical Shift
A very important NMR parameter that provides information on the local electronic environment of nuclei in molecules. Chemical shifts are measured on the frequency axes of NMR spectra.

Chemical Shift Mapping
An approach to characterizing interactions between molecules by determining which sites have their chemical shifts perturbed when a ligand binds to a macromolecule. Since chemical shifts reflect the local environment, only signals close to the binding site are perturbed following ligand binding or conformational changes.

HSQC Spectroscopy
Short for heteronuclear single quantum coherence spectroscopy. This is a very powerful 2D NMR method that provides a useful ''fingerprint'' spectrum that can be used in binding studies.

Isotope Labeling
The use of stable isotopes (e.g. ^{13}C, ^{15}N) to enhance the prevalence of NMR-active nuclei in a protein to allow a sophisticated range of multinuclear NMR experiments to be carried out. Labeled proteins are easily produced using recombinant methods.

Multidimensional NMR
NMR experiments that result in spectra having multiple frequency axes so that spectral overlap is reduced. One-dimensional NMR spectra have one frequency axis (e.g. ^{1}H chemical shift) and one intensity axis, while in 2D NMR there are two frequency axes, with peak intensities normally represented in contour form. For example, in 2D HSQC spectra, the frequency axes often correspond to ^{1}H and ^{15}N chemical shifts.

NMR Screening
A generic term for a range of NMR techniques that identify ligands (usually as part of a library of compounds) that bind to a target macromolecule.

NOE (Nuclear Overhauser Effect)
An NMR parameter that provides information on distances between nuclei. This distance information in turn can be used to determine the three-dimensional structures of molecules, particularly peptides and proteins. NOEs are derived from intensities in NOESY spectra.

Pulse Sequence
An array of radio-frequency pulses that is used to perturb the nuclei in a sample in a defined way so as to produce a particular type of NMR spectrum. For example, different pulse sequences are used to generate NOESY or HSQC spectra.

Structure-based Design
An approach to designing drugs on the basis of knowledge of the structure of a target macromolecule and/or macromolecule–ligand complexes.

NMR spectroscopy is a powerful technique for determining the structures of molecules in solution. It involves placing a sample in a powerful magnetic field and irradiating it with radio waves of defined frequency. The emitted signals provide information about the local molecular environments of nuclei in the sample, from which structures can be derived. NMR can also be used for determining interactions between molecules and is particularly useful for determining the nature of binding interactions between ligands and macromolecules. This information is very important in drug design: by understanding how bioactive molecules interact with a target protein or nucleic acid it is, in principle, possible to design ligands with improved affinity and specificity, which may make useful drug leads. In addition to this structure-based approach to drug design, NMR is also useful as a screening tool in drug discovery programs to identify ligands that bind to target macromolecules.

1 Introduction

NMR spectroscopy has been widely used as a frontline tool in the pharmaceutical industry for several decades. In the past, the main use of NMR was in the structural characterization of organic molecules synthesized in the course of medicinal chemistry programs. Indeed, medicinal chemists have long regarded NMR as the premier tool for structure characterization, to confirm the identity of intermediates, or to determine the conformation of lead molecules. Over the last decade, major developments in both instrumentation and methods have resulted in this traditional use of NMR in the pharmaceutical industry being augmented by a range of exciting new applications. Two of the most important of these are the use of NMR in structure-based drug design and in screening for drug discovery. Both applications differ from the traditional use of NMR in that the macromolecular binding partner of the medicinal compound is now included in the mixture to be analyzed; that is, current applications of NMR in drug discovery are predominantly focused on the *interaction* between drug molecules and their macromolecular targets.

The aim of this chapter is to describe how NMR spectroscopy is used in modern drug discovery. The term *discovery* is used generically throughout to include processes that involve rational drug design as well as those that involve discovery through NMR screening. The latter is a relatively recent development and refers to the use of NMR as a tool to screen a compound library to identify molecules that bind to a chosen macromolecular target. Of course, the distinction between ''design'' and ''discovery'' is often quite blurred. This is nowhere more evident than in the recently developed SAR-by-NMR approach, in which the discovery of several weakly bound ligands from a screening program is intimately linked to a design process to chemically join them. SAR-by-NMR represents an exciting new technique for lead generation and is described in more detail later in this chapter.

Drug design/discovery represents only the first stage in the drug development process. There are many other steps that need to be taken once a lead molecule has been designed or discovered. Although other stages of the process, including lead optimization, toxicity studies, preclinical investigations, and clinical monitoring, do not fall within the scope of this chapter, it is worth mentioning that NMR spectroscopy contributes significantly across the whole spectrum of drug development, right through into the clinical domain. For example, NMR spectroscopy has been applied for the detection of drug metabolites in biological fluids and magnetic resonance imaging, which is based on the fundamental principles of NMR, plays an important role in clinical investigations. It is increasingly being used to monitor the functional outcomes of drug therapy. We will briefly address these broader applications of NMR before returning to the main topic of NMR in drug discovery.

1.1 Overview of Drug Development

To give an overview of the breadth of applications of NMR, Fig. 1 summarizes the drug development process and indicates the role of NMR at various stages. Drug development is an iterative process and can be simplified by representing it with

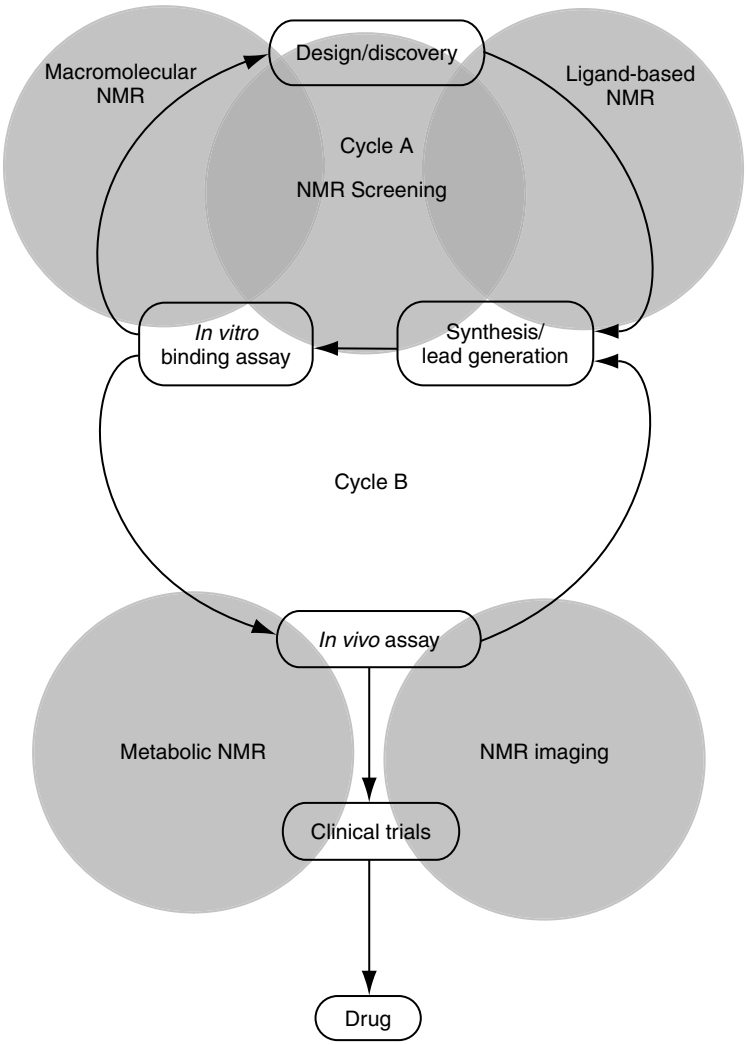

Fig. 1 Overview of the drug development process and summary of various types of NMR experiments that contribute at different stages.

two interconnected cycles of activity. Cycle A involves the design or discovery of an initial lead followed by its synthesis and bioassay. On the basis of the initial assay results, there may be several loops around this cycle before commencing the *in vivo* studies represented in Cycle B. At this stage, consideration of bioavailability, metabolism, and pharmacokinetic profiles must be made and this may involve synthetic modifications of the lead molecules to improve their druglike properties. Again, several loops around Cycle B may be necessary before one or more development candidates are identified. Ultimately one or more of these development candidates are identified for progression through clinical trials.

As indicated in Fig. 1, it is convenient to envisage five broad categories of NMR experiments that may contribute to this overall drug development process.

1. *Small molecule, or ligand-based, NMR.* This involves studies of drugs and drug leads, typically organic molecules with a molecular weight <500 Da, but also including small proteins of up to a few kDa. These studies may be used to characterize natural products or synthetic drug leads, or to determine their conformation.
2. *Macromolecular NMR.* This involves studies of the macromolecular targets of drugs, typically to determine their three-dimensional structure and/or the nature of their complexes with ligands.
3. *NMR screening.* This involves the use of NMR to identify lead molecules that bind to macromolecular targets. These studies typically involve both small molecules and macromolecules and seek to detect the presence of binding interactions between them.
4. *Metabolic NMR.* This involves studies of endogenous molecules whose concentrations may be modified by drug treatment, or studies of the metabolites of drugs themselves.
5. *NMR imaging.* Such studies provide anatomical information in an animal model or human patient. This includes, for example, monitoring the size of plaques or tumors in the brains of Alzheimer's or cancer patients, respectively, during drug therapy.

It is clear from these descriptions that NMR covers a wide range of applications in the pharmaceutical industry, although for the remainder of this chapter we will focus on NMR in the drug design/discovery phase of drug development, that is, on categories 1 to 3 of the preceding list. Together, the studies in categories 1 and 2 may be classified as structure-based design, whereas category 3 relates to drug discovery.

1.2 Scope of Chapter

Our aim is to give a broad overview on the use of NMR as a tool in structure-based design and in screening approaches to drug discovery. This chapter also contains a description of the relevant NMR methods, which are highlighted by illustrative examples. We briefly describe the instrumentation required for such studies and discuss emerging trends in the field. This includes developments in the field of drug discovery in the postgenomic era, which are likely to have an impact on the way in which NMR is used, as seen, for example, by the recent interest in structural genomics programs. NMR instrument developments are also described. For example, recent advances in cryoprobe technology promise to dramatically increase the sensitivity of NMR spectroscopy and also increase its application across the pharmaceutical industry. Finally, a section outlining some of the practical considerations in structure-based design and screening is included. Future directions in this field are mentioned throughout the discussion.

There are a number of reviews that describe applications of NMR in drug discovery or screening, and the reader is referred to these for additional information. Recent books covering aspects of NMR in drug design are also available.

It is assumed that most readers would be familiar with the basic principles of NMR. However, for completeness and to define some of the terms that will be used in this

chapter it is useful to give a brief overview of the principles.

1.3 Principles of NMR Spectroscopy

The underlying basis of NMR is that when nuclei with a nonzero spin quantum number are placed in a magnetic field, they take up one of a discrete number of quantized states. The application of radio-frequency (rf) energy produces transitions between these states. The energy changes associated with these transitions are detected as small voltages induced in a receiver coil, which are subsequently amplified, digitized, and processed to yield spectra, as illustrated in Fig. 2. The most commonly studied NMR-active nucleus is the proton, ^{1}H, but in modern NMR experiments ^{2}H, ^{13}C, and ^{15}N nuclei are also very important. For these heteronuclei, it is common to isotopically enrich the sample because of their low natural abundance. This is particularly important for studies of proteins, as will become apparent later in this chapter. Occasionally, other nuclei find specialist applications. For example, in fluorine-containing drugs it is possible to use sensitive ^{19}F-NMR signals to monitor interaction with target proteins, as described later in this chapter.

In modern spectrometers, the rf energy is supplied in the form of short pulses (typically, ~10 μs) that simultaneously excite all nuclei of a given isotope type (e.g. all protons or all ^{13}C nuclei). Nuclei of a given isotope, which are in different chemical environments by virtue of their atomic locations in the molecule, have slightly different resonance frequencies and lead to different oscillating voltages in the receiver coil. The resultant combined signal, termed a *free induction decay* (FID), is Fourier transformed to give a spectrum that is basically a plot of peak intensity versus frequency, with one peak for each chemically distinct nucleus. These features are schematically illustrated in Fig. 2. The frequency axis is termed the *chemical shift* because it reflects the local chemical environment of each nucleus. The range of chemical environments of nuclei in a molecule is such that chemical shifts range up to only a few hundred parts per million (ppm) of the base resonance frequency for ^{13}C and ^{15}N. For ^{1}H the range is smaller, covering only about 10 ppm. Despite this small range, chemical shifts provide valuable diagnostic information on

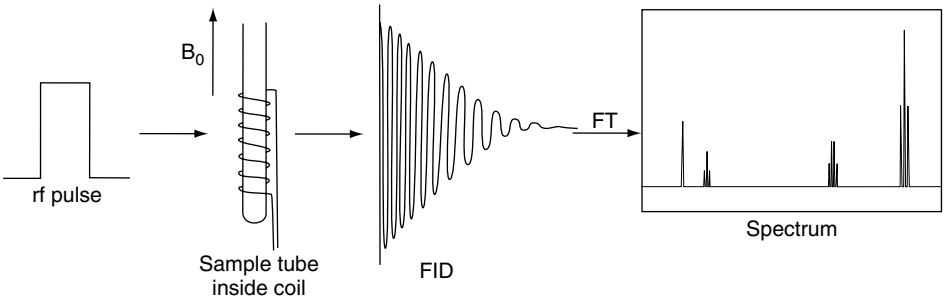

Fig. 2 Overview of the principles of NMR spectroscopy. Polarization of nuclear spins by a magnetic field is perturbed by application of a radio-frequency (rf) pulse. The resultant signal is Fourier transformed, to yield a spectrum reflecting the number and environments of nuclei in the sample.

the environment of the nucleus that is giving rise to the signal.

The chemical shift is an extremely important NMR parameter, but there are many other parameters that can be discerned from NMR spectra. Indeed, NMR is unique among many forms of spectroscopy in that there are so many parameters associated with a spectrum other than just peak intensity and frequency. These include coupling constants, which provide information on local conformations and also on molecular connectivities; nuclear Overhauser effects (NOEs), which provide information on internuclear distances; and relaxation parameters, which provide information on molecular dynamics. Table 1 summarizes the main NMR parameters that may be measured and highlights their applications in the drug discovery process.

The following sections of this chapter provide specific examples of how these various parameters are useful in the drug discovery process. Before doing this, though, it is useful to consider some of the limitations of one-dimensional (1D) NMR spectroscopy, particularly when the detected nucleus is ^{1}H, as is most commonly the case. With one signal coming from each chemically distinct proton and with those signals spread only over 10 ppm, it is clear that spectral overlap can potentially be a major problem for anything but the simplest of molecules. The development of higher field NMR spectrometers, which effectively provide greater dispersion in the frequency dimension, has contributed significantly to overcoming this limitation and increasing the application of NMR for studying pharmaceutically relevant molecules. In addition to such instrumental developments, methodological advances have also played a key role in extending the use of NMR. Multidimensional NMR methods have revolutionized biomolecular NMR spectroscopy by removing the limitations of a single frequency dimension, leading to the development of 2D, 3D, and 4D spectra.

A simple way of illustrating multidimensional NMR is through reference to heteronuclear correlation spectroscopy, in which two or more separate frequency dimensions are correlated with one another. For example, a particularly valuable 2D experiment is $^{1}H-^{15}N$ heteronuclear single quantum correlation (HSQC)

Tab. 1 NMR parameters and their applications in drug design/discovery.

Parameter	***Information provided relevant to drug design***
Chemical shift	Reflects local chemical environment; provides a fingerprint marker of structure (particularly in HSQC spectra)
Coupling constants	Conformational analysis, establishing molecular connectivity
Nuclear Overhauser effect	Determining interproton distances, three-dimensional structures
Relaxation times	Molecular dynamics
Line shape	Detecting and quantifying chemical-exchange processes
Peak intensities	Reflect relative number of nuclei, molecular symmetry
Amide-exchange rates/temperature coefficients	Hydrogen bonding or solvent exposure of amide protons

spectroscopy, in which the resultant spectrum has two frequency axes, corresponding to ^{1}H and ^{15}N frequency dimensions, and one intensity axis. Analogous $^{1}H-^{13}C$ HSQC spectra are also widely used. Such spectra are normally represented with the intensity axis in contour form so that they may be drawn in two dimensions as a set of contour peaks. Spectral peaks occur for pairs of $^{15}N/^{1}H$ or $^{13}C/^{1}H$ nuclei that are directly bonded to one another, and with each frequency being characteristic for the local chemical environment, HSQC spectra represent a relatively simple but highly characteristic fingerprint of the sample. Figure 3 shows the relationship between 1D and 2D spectra for the immunosuppressive drug cyclosporin, and includes a region of both the $^{1}H/^{15}N$ and $^{1}H/^{13}C$ HSQC spectra. In HSQC spectra, overlap problems are alleviated because, even if two protons have the same chemical shift and would hence be overlapped in a 1D spectrum, chances are that the respective heteronuclear signals will not be overlapped, allowing the signals to be resolved in the 2D spectrum. HSQC spectra are widely used in NMR-based drug screening and we will return to them later.

Multidimensional NMR spectra are not restricted to cases where the separate frequency axes encode signals from different nuclear types. Indeed, much of the early work on the development of 2D NMR was performed on cases where both axes involved ^{1}H chemical shifts. The main value in such spectra comes from the information content in cross peaks between pairs of protons. In COSY-type spectra (COSY = COrrelation SpectroscopY), cross peaks occur only between protons

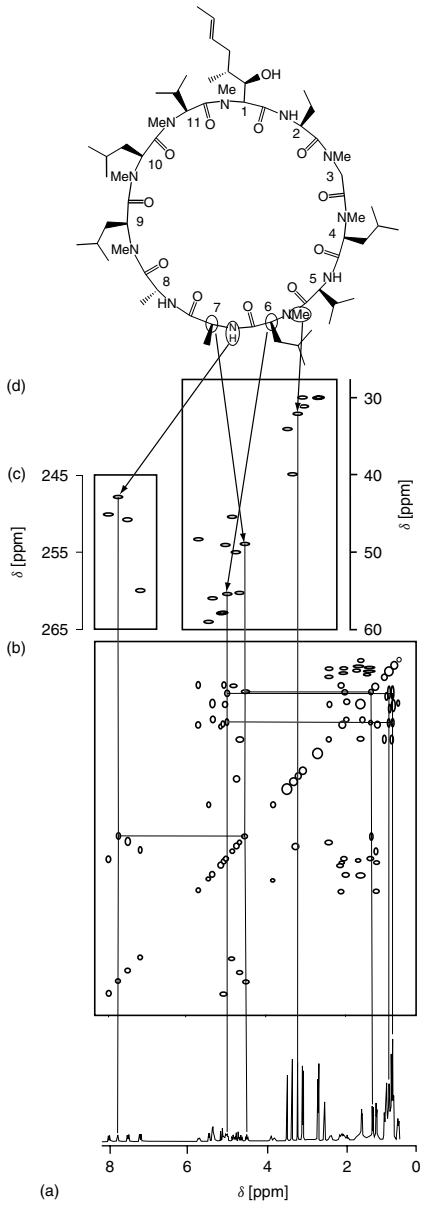

Fig. 3 A schematic representation of the (a) 1D ^{1}H; (b) 2D DQF-COSY; (c) $^{15}N/^{1}H$-HSQC; and (d) $^{13}C/^{1}H$-HSQC spectra of the immunosuppressive agent cyclosporin. Example resonances/correlations from residues 6 and 7 have been highlighted to illustrate the assignment process.

that are scalar coupled (i.e. within 2 or 3 bonds) to each other, whereas in NOESY (Nuclear Overhauser Effect SpectroscopY), spectra cross peaks occur for protons that are physically close in space (<5 Å apart). A combination of these two types of 2D spectra may be used to assign the NMR signals of small proteins and provides sufficient information on internuclear distances to calculate three-dimensional structures. Figure 3 includes a panel showing the COSY spectrum of cyclosporin and highlights the relationships between 1D ^{1}H-NMR spectra and corresponding 2D homonuclear (COSY) and heteronuclear (HSQC) spectra.

Homonuclear 2D spectra are generally applicable for the study of proteins up to approximately 80 amino acids in size. For larger proteins, the increased number of signals leads to overlap problems and, in addition, COSY-type spectra suffer from poor sensitivity when the signal linewidths are of the same order as or larger than ^{1}H, ^{1}H scalar coupling constants. Such limitations are reduced by the use of spectra of higher dimensionality (i.e. 3D or 4D spectra) that are based on correlations involving heteronuclear rather than homonuclear coupling constants. Such spectra are important in the structure determination process for larger proteins and are typically recorded for samples that incorporate uniform labeling with ^{15}N, or both ^{13}C and ^{15}N nuclei. Multidimensional spectra that involve irradiation of ^{1}H, ^{13}C, and ^{15}N nuclei are referred to as *triple resonance spectra*.

The details of how multidimensional spectra are obtained is beyond the scope of this chapter, but it suffices to say that, like most other modern NMR experiments, they involve irradiation of the sample with a set of rf pulses of defined length, frequency, and phase, with specific interpulse delays. The pulse programs for such experiments are commonly provided with the spectrometer as part of a standard library of experiments and may easily be run by novice users after input of an appropriate set of parameters to define the relevant spectral widths and type of experiment required.

The above discussion provides a basic overview of some of the methods important in modern NMR spectroscopy. Before examining specific applications in drug discovery, it is useful to describe the instrumental requirements for such studies.

1.4 Instrumentation

NMR spectrometers constitute a powerful and homogeneous magnet, a radio-frequency console for generating appropriate rf pulses, a probe for applying this rf energy to the sample and receiving the resultant signals, and a computer console for controlling the experiments and acquiring the resultant data. These features are summarized in Fig. 4. Spectrometers are normally specified in terms of the resonant frequency of protons at the given magnetic field (e.g. 500 MHz corresponds to a magnetic field of 11.7 T). Both sensitivity and dispersion of signals increase with increasing magnetic field.

There have been some major breakthroughs in both NMR instrumentation and methodology over the last decade, which has greatly increased the utility of NMR for drug discovery applications. These are summarized in Table 2, which also includes some of the earlier milestones in the development of NMR. Most notable among recent innovations are the use of pulsed-field gradient methods for improving spectral quality and allowing new types of experiments

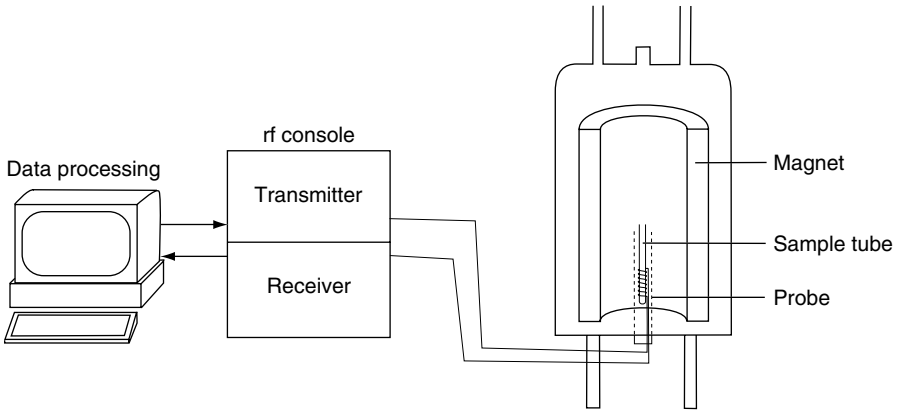

Fig. 4 Block diagram of a modern NMR spectrometer. These systems use superconducting magnets that are based on a solenoid of a suitable alloy (e.g. niobium/titanium or niobium/tin) immersed in a dewar of liquid helium. The extremely low temperature of the magnet itself (4.2 K) is well insulated from the sample chamber in the center of the magnet bore. The probe in which the sample is housed usually incorporates accurate temperature control over the range typically of 4 to 40 °C for biological samples. The rf coil in the probe is connected in turn to a preamplifier, receiver circuitry, analog-to-digital converter (ADC), and a computer for data collection.

Tab. 2 Milestones in the development of NMR spectroscopy.

Year	*Development*	*Nature*
1970	FT NMR	Instrumental
1975	Superconducting magnets	Instrumental
1980	2D NMR	Methodological
1985	Protein structure determination	Methodological
1990	Isotope labeling/multidimensional NMR	Methodological
1990	Pulsed-field gradients	Instrumental/methodological
1995	NMR screening	Methodological
1997	TROSY	Methodological
1998	LC-NMR/ LCMS-NMR	Instrumental
2000	Cryoprobes	Instrumental

to be performed, transverse relaxation-optimized spectroscopy (TROSY) methods for increasing the size of macromolecules that can be examined, and cryoprobes for enhancing sensitivity. The development of cryoprobes has resulted in the biggest single gain in sensitivity over recent years, effectively giving 500-MHz spectrometers the sensitivity of 800-MHz spectrometers (although without the gain in resolution!). The enhanced sensitivity is obtained by cooling the receiver coil and associated circuitry to near liquid helium temperatures, thereby reducing thermal noise. There were considerable technical barriers to be overcome in developing such probes because of the large difference in temperature between the receiver coils and the sample, which are only a few millimeters apart. These barriers have now

been overcome and cryoprobes are being installed in a large number of laboratories. They are also becoming available for higher field systems (900 MHz), thus providing further sensitivity gains.

Although the basic configurations of instruments tailored for structure-based design or for NMR drug screening are similar, there are some minor differences. For structure-based design applications, a relatively high field spectrometer is required (>500 MHz), usually equipped with three or four radio-frequency channels for the simultaneous irradiation of ^{1}H, ^{13}C, ^{15}N, and in some cases ^{2}H nuclei. The greatest sensitivity and dispersion are obtained with the highest possible magnetic field. Instruments of up to 900 MHz are currently available but, at the time of writing, only a few have been installed. Numerous 800-MHz systems dedicated to structure-based design have been installed in pharmaceutical laboratories. The high field instruments provide another advantage in that TROSY experiments can be used to produce a marked improvement in spectral quality for larger proteins. Such developments promise to push higher the size of proteins whose structure can be determined by NMR.

For NMR drug screening programs, the basic requirement of a spectrometer of 500 MHz or greater remains, but in addition, an interface that allows the spectrometer to sample a library of compounds of potential binding ligands needs to be present. This may be done either by use of a discrete sample changer or a flow-type system. Flow systems have the potential advantage of increased throughput and also have the potential disadvantage of precipitation of protein samples. In practice, this appears not to have been a major problem and both types of systems are in use in the pharmaceutical industry. Cryoprobes allow dramatically enhanced sensitivity gains, which bring particular advantages to the study of macromolecule–ligand interactions used in screening programs.

Pulsed-field gradients have become integral to most modern NMR spectrometers and are routinely used both for structure determination and screening experiments. Another recent development has been the interface of NMR spectrometers with other instrumentation such as liquid chromatography (LC) and/or mass spectrometry (MS).

1.5 Applications of NMR in Drug Design and Discovery

Our focus here is on the use of NMR in the discovery and design phase of drug development. The major role of NMR in the *design* process comes about by its exquisite ability to provide structural information, whereas the major role of NMR in *discovery* comes through its use as a screening tool to detect the binding of novel ligands to macromolecular targets. As already noted, the latter application is a relatively recent development but has created much interest in the pharmaceutical industry and promises to significantly enhance applications of NMR in this industry. The impact of the methodology is already becoming evident even at this early stage, with several SAR-by-NMR-derived leads currently in clinical development. As already noted, though, the discovery and design phases are often intimately connected, with lead molecules discovered in screening programs routinely being optimized by use of structure-based design approaches (Fig. 5).

In the context of this chapter, structure-based design refers to the process of

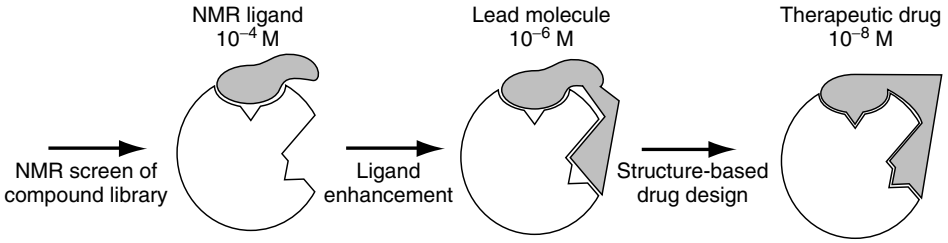

Fig. 5 A summary of the relationship between NMR screening and structure-based design. (Adapted from Peng, J.W, Lepre, C.A., Fejzo, J., Abdul-Manan, N., Moore, J.M. (2001) *Methods Enzymol.* **338**, 202.)

determining the three-dimensional structure of a lead molecule or macromolecular target, or determining the structure of the macromolecule–ligand complex, and using this information to design new drugs. The questions that may be asked when embarking on structure-based design projects are:

- What are the solution and bound conformations of the ligand?
- What is its charge/tautomeric state?
- Which functional groups bind to the receptor and what charge state are they in?
- What is the structure of the receptor?
- Which parts interact with the ligand?
- What is the geometry of the ligand–receptor complex?
- What are the kinetics of binding and are there dynamic motions of ligand, receptor, or the complex?

Table 3 summarizes these and other questions and indicates the type of NMR approaches that can provide answers. Remaining sections of this chapter are organized around the headings identified in Table 3.

In considering these questions, it is convenient to distinguish between ligand-based design, where the structural focus is on the small lead molecule, and receptor-based design, where the aim is to determine the structure of the macromolecular target. The NMR methods used in ligand-based design have been well established for many years, based on the use of NMR by organic and natural product chemists for more than four decades. However, there have been some important recent advances in NMR methods such as the use of pulsed-field gradients, and in the combination of NMR with other technologies such as LC and MS, which promise to enhance applications in this field. The use of NMR to determine the three-dimensional structures of macromolecules is a newer field, which commenced only in 1985 and is still rapidly evolving. NMR screening is a still newer approach, developed around 1996. Ligand-based and receptor-based design are examined in Sects. 2 and 3, respectively, and screening-based approaches are examined in Sect. 4.

2 Ligand-based Design

Many naturally occurring molecules have potent bioactivity that renders them useful as leads in the drug design process. These may be naturally occurring hormones, neurotransmitters, or other endogenous

Tab. 3 Information on ligands, macromolecules and their complexes sought in structure-based design and relevant NMR technologies used to derive this information.

Target	*Information*	*NMR Technology*
Ligand	Solution conformation	1D/2D NMR
	Charge/tautomeric state	Chemical shift/titrations
	Solution dynamics	Line-shape/relaxation analysis
	Pharmacophore models	All of the above, and TrNOE, of multiple ligands
	Bound ligand conformation	TrNOE
Macromolecule	3D structure	2D/3D/4D NMR
	Macromolecular dynamics	Relaxation time measurements
	Structure of articulated macromolecules (e.g. multimeric or membrane-bound receptors)	TROSY
Ligand–macromolecular complex	Stoichiometry of complex	Chemical-shift titration
	Kinetics of binding	Line width, titration analysis
	Location of interacting sites	HSQC, isotope editing
	Orientation of bound ligand	NOE docking
	Bound ligand conformation	TrNOE
	Structure of complex	3D/4D NMR
	Dynamics of complex	Relaxation time measurements

molecules, or they may be bioactive molecules from plants or microorganisms. Furthermore, screening programs on synthetic compound libraries frequently result in the discovery of bioactive molecules, which then become starting points in drug design. The general aim of ligand- or analog-based design is to determine the structure and conformation of a known bioactive molecule and then mimic this conformation in a designed lead compound, with the aim of improving its activity or druglike properties. The following sections examine various aspects of ligand-based design and illustrate them with examples.

2.1 Structure Elucidation

If the bioactive molecule is a synthetic product, its structure may be rapidly deduced by a simple comparison of NMR parameters (often combined with MS) of the product relative to those of the known precursor, to see whether the desired chemical transformation has taken place. If the bioactive compound is an unknown molecule discovered in an active fraction in bioassay-guided screening, then the first step is to elucidate its structure. Typical molecules that form the basis of such natural products-based drug discovery studies include "organic" natural products as well as small peptides and proteins. The approaches to structure elucidation for natural products and peptides/proteins are a little different from each other and are described in turn.

2.1.1 Structure Elucidation of Natural Products

In the case of nonpeptidic natural products, the main structural focus initially is

to elucidate the carbon framework. This normally involves a combination of 1D ^{1}H and ^{13}C-NMR, followed by homonuclear (DQF-COSY, TOCSY, ROESY, or NOESY) and heteronuclear (HSQC, HMBC) 2D experiments. Heteronuclear multiple bond correlation (HMBC) spectra are particularly valuable because they assist in tracing the backbone of the molecule. Such spectra display cross peaks between a ^{13}C nucleus and protons connected within two or three bonds and, in doing so, provide valuable information on molecular connectivity. Figure 6 shows typical HMBC correlations seen for selected regions of taxol, a plant-derived natural product that is currently a leading treatment for breast and ovarian cancers. Although the structure of taxol itself was originally deduced from a combination of X-ray crystallography on a degradation product and a range of ^{1}H and ^{13}C spectra in the 1970s, before HMBC spectra had been invented, HMBC spectra have been widely used for studies of the many taxol derivatives that have been examined in the last decade.

Elucidation of the carbon framework of natural products often yields substantial information about the three-dimensional structure at the same time, but if there are remaining questions on the stereochemistry of chiral centers or other factors affecting the three-dimensional structure, these can usually be resolved from NOESY spectra and/or an analysis of coupling constants. We will return to the taxol example later in Sect. 2.2 when describing conformational analysis.

2.1.2 Structure Determination of Bioactive Peptides

In contrast to the process described for organic molecules, the structure elucidation of peptide-based natural products involves two distinct steps: (1) the elucidation of the primary structure (amino acid sequence) followed by (2) the determination of secondary/tertiary structure. The primary structure determination is

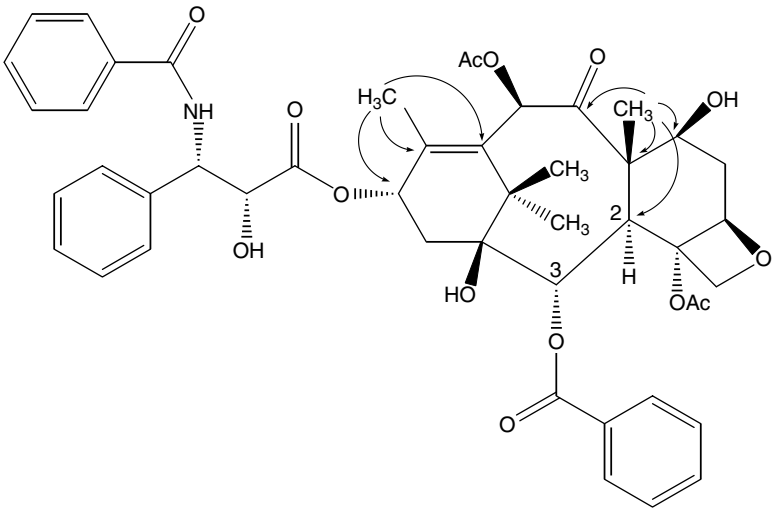

Fig. 6 Illustration of the HMBC correlations (arrows) used to assign the positions of two of the methyl quaternary methyl groups in taxol.

routinely done through Edman sequencing, or more recently by MS−MS methods. NMR plays a key role in the elucidation of the secondary and tertiary structure of peptides, mainly based on 2D homonuclear NMR spectroscopy. A combination of DQF-COSY and TOCSY (TOtal Correlation SpectroscopY) spectra are used to assign spin systems to amino acid types and then NOESY spectra are used to sequentially assign the resonances to individual protons in the peptide. The three-dimensional structure is then determined by deriving a series of internuclear distance restraints from the NOESY spectrum and using them in a simulated annealing algorithm to calculate a family of structures consistent with them.

Because the structure determination of peptides and proteins represents a very important contribution of NMR to the drug development process, it is informative to describe the process in more detail. To do this, we will use the recently developed peptide-based drug MVIIA as an example.

2.1.2.1 **NMR structure of Prialt® (MVIIA): a novel treatment for pain.** MVIIA, now known as Prialt®, is a 25-amino acid peptide originally discovered from the venom of the marine cone snail, *Conus magus*. Like other ω-conotoxins, it is a potent blocker of N-type calcium channels, giving it a wide range of potential therapeutic applications. When delivered intrathecally (i.e. through spinal infusion), it is approximately 1000 times more potent than morphine as an analgesic and has great potential for the treatment of intractable cancer pain. Figure 7 shows the peptide sequence and illustrates selected regions of the TOCSY and NOESY spectra.

As seen in Fig. 7, the TOCSY experiment is useful for classifying spin systems to amino acid type, with typically the most useful region being the ''skewers'' emanating from individual NH shifts (~7–10 ppm). For each NH proton in the peptide, a series of cross peaks to the α, β, and other side-chain protons is observed and these patterns define the spin system as belonging to a particular type of amino acid. Note, however, that there is some degeneracy in the resultant patterns. The NH side-chain pattern is truncated if there is a break of more than three bonds between protons within the spin system. This means, for example, that the skewers for aromatic residues extend only as far as the β-protons and they therefore appear similar to other ''AMX'' residues such as Cys, Ser, Asp, or Asn. Nevertheless, the ability to assign signals to either individual amino acid types or to the AMX group is a useful starting point in the assignment. However, such spectra provide no information about the sequential location of an amino acid if it is not unique in the sequence. These sequential assignments are obtained from the NOESY spectrum, as illustrated in the sequential walk shown in the middle panel of Fig. 7. The aim of the sequential assignment process is to locate adjacent amino acid spin systems, principally through a cross peak between the αH proton of one residue (i) and the NH of the following residue ($i + 1$), often denoted as dαN(i, $i + 1$). Additional support for the assignment is usually also sought in dβN(i, $i + 1$) and dNN(i, $i + 1$) correlations. At the early stages of an assignment, it is impossible to be certain whether a particular cross peak is a sequential or longer range cross peak; however, as the assignment procedure progresses, ambiguities become resolved. The assignment process is generally highly convergent, in that once a series of correct assignments is

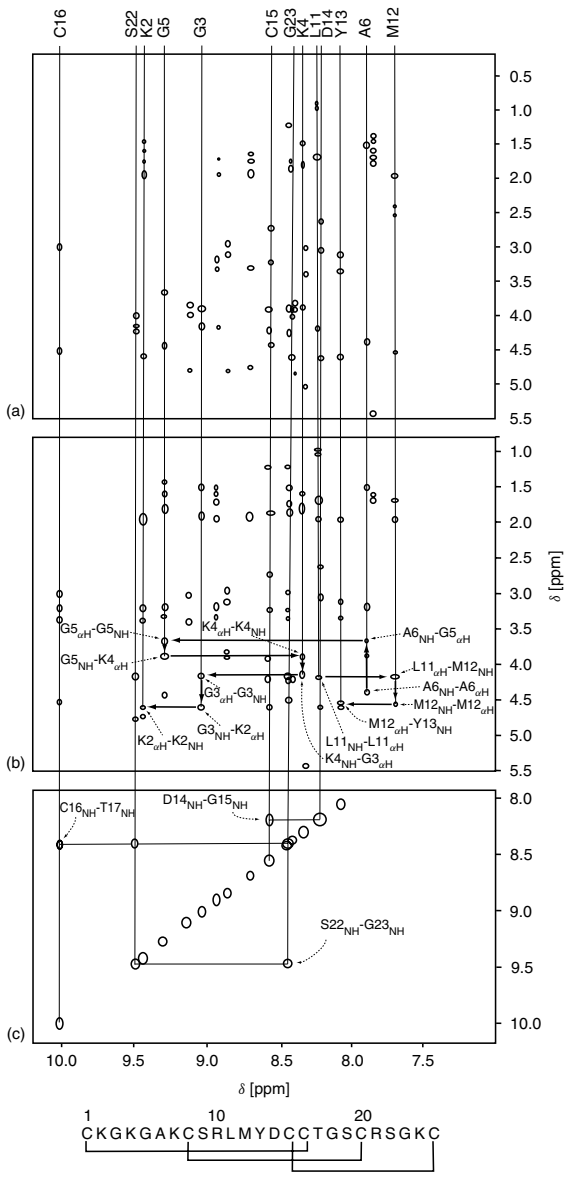

Fig. 7 Schematic representations of 2D-NMR spectra of the conotoxin MVIIA. (a) The fingerprint region of the TOCSY spectrum with selected spin systems marked. (b) Fingerprint region of the NOESY spectrum showing two (K2-A6 and L11-Y13) sequential walks. (c) NH−NH region of the NOESY spectrum showing correlations between the NH protons of D14 and G15; C16 and T17; and S22 and G23.

made, the number of choices for remaining cross peaks diminishes, in principle making their assignment easier.

Because peptides are polymers of amino acid units, the repeated NH, Hα, and side-chain protons tend to fall in characteristic chemical-shift ranges that can be useful in looking for patterns to identify amino acid types. Table 4 shows the typical chemical shifts for each of the 20 common amino acids when located in a ''random-coil'' environment. It is important to stress that

The backbone shifts (αH and NH, ppm) are from Wishart, D.S., Bigam, C.G., Holm, A., Hodges, R.S., Sykes, B.D. (1995) ^{1}H, ^{13}C and ^{15}N random-coil NMR chemical shifts of the common amino acids. I. Investigations of nearest-neighbor effects, *J Biomol NMR* **5**, 67–81. The remaining shifts are from Wüthrich, K. (1986) *NMR of Proteins and Nucleic Acids*, Wiley, New York.

these shifts can vary quite considerably in structured proteins (by up to several ppm) and are more useful for pattern recognition purposes than for exact identification of a particular residue. In the case of the Hα protons, the differences between the actual shifts in a structured protein and these random-coil values have an additional important use, in that they provide an indication of the local secondary structure. Intuitively, the further a chemical shift is from a random-coil value, the more likely it is attributed to the corresponding atom being in a structured environment.

After the assignment is complete, it is possible to derive substantial information about the secondary structure from an analysis of chemical shifts, coupling constants, and NOEs, even before the three-dimensional structure calculations are commenced. Figure 8 shows a typical summary of the relevant NMR information, again using the data for MVIIA as an example. Trends in these data provide a general indication of major elements of secondary structure. For example, a series of strong dαN(i, $i+1$), relative to dNN(i, $i+1$) NOEs often indicates an extended or β-type structure, whereas strong dNN(i, $i+1$) NOEs indicate local helical structure or turns. Large JαN coupling constants (>8.5 Hz) are associated with extended structure and small ones (<5 Hz) are associated with helical structure. Similarly, deviations of chemical shifts from random-coil values, often represented in terms of ''chemical shift indices,'' indicate extended (positive values) or helical structure (negative values).

An additional useful parameter is the exchange rate of amide protons after dissolution of the sample in D_2O. Slowly exchanging amide protons indicate protection from solvent and possible involvement in intramolecular hydrogen bonds associated with elements of secondary structure. All of the NMR and slow exchange data can be consolidated to give an accurate representation of secondary structure, as indicated in the lower panel of Fig. 8. In the case of MVIIA, a triple-stranded β-sheet may be deduced on the basis of the local NOE, coupling, chemical shift, and amide-exchange NMR data.

Once all peaks in the 2D spectra have been assigned, cross peaks in the NOESY spectrum are used to derive a series of interproton distance restraints. These are then used in a simulated annealing algorithm to calculate a family of 3D structures consistent with the input restraints. Figure 9 shows two commonly used methods of representing such NMR-derived structures, either as a stereoview of the superimposed family of structures or as a ribbon diagram, in which elements of secondary structure are highlighted. For the latter representation, the lowest energy or average member of the ensemble is often chosen as representative of the structure. It is important, however, to examine the full ensemble to gain a complete understanding of the structure. Regions of disorder in the ensemble can be indicative of a lack of sufficient distance restraints, perhaps attributable to overlap or assignment errors, or may be related to local flexibility.

In the case of MVIIA, the peptide itself is being clinically developed as the active drug for administration through the intrathecal (spinal infusion) route. However, in general, peptides have a range of potential disadvantages as drugs, including poor bioavailability and susceptibility to proteolytic breakdown. Thus, for many cases involving peptide-based leads, the structural information of the type described above might be used as a starting point

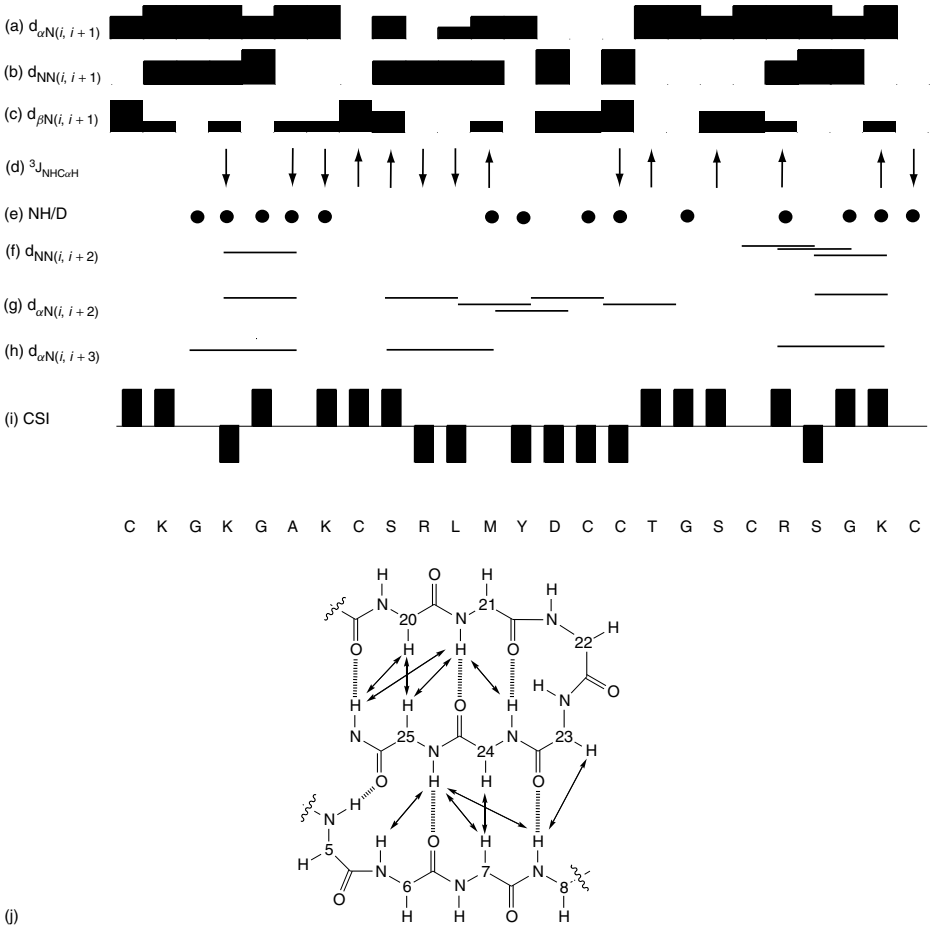

Fig. 8 A summary of the NMR data observed for MVIIA. (a) Hα−NH sequential NOEs. (b) NH−NH sequential NOEs. (c) Hβ−NH sequential NOEs. (f−h) Other short-range NOEs. The thickness of the bar indicates the strength of the observed NOE (weak, medium, or strong). (d) Three-bond NH−Hα coupling data, where upward-pointing arrows indicate a large coupling (>8 Hz) and downward-pointing arrows indicate a small coupling (<5 Hz). (e) H/D exchange data, where a filled circle represents a slow exchanging NH. (i) Chemical-shift index (CSI) data. The CSI uses a scoring system that compares Hα shifts to random-coil chemical shifts. A sequence of consecutive +1 scores is indicative of β-structure, whereas a sequence of consecutive −1 scores suggests helical structure. (j) The β-sheet of MVIIA. Double-headed arrows indicate observed NOEs and broken lines indicate proposed H bonds.

to design smaller constrained peptides or nonpeptidic mimics. This is the case, for example, in the development of endothelin antagonists described below.

2.1.2.2 **Endothelin as a lead in ligand-based design.** Endothelin (ET), shown in Fig. 10, is a 21-amino acid endothelial-derived constricting factor that has gained

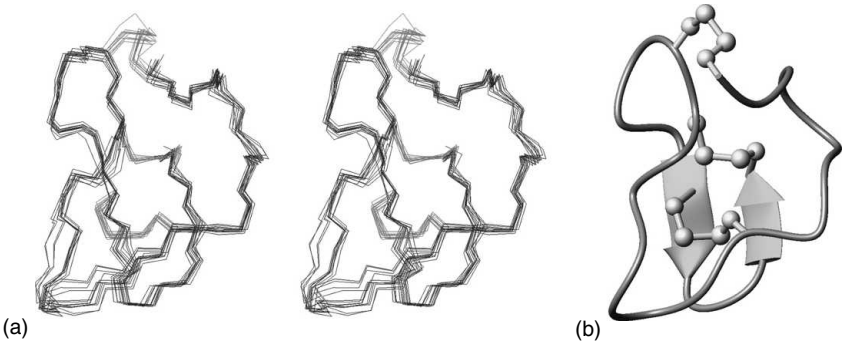

Fig. 9 (a) A stereoview of the superimposed backbone structures of the 20 lowest energy conformations for MVIIA (reproduced from Nielsen, K.J., Thomas, L., Lewis, R.J., Alewood, P.F., Craik, D.J. (1996) *J. Mol. Biol.* **263**, 297). (b) Ribbon diagram of MVIIA.

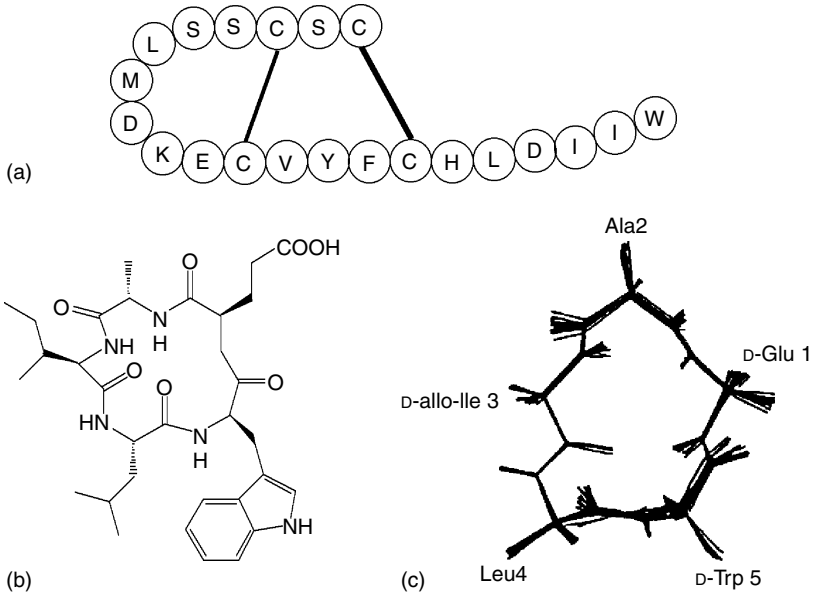

Fig. 10 (a) Primary sequence and disulfide connectivities of endothelin-1 (ET-1). (b) Primary structure of the cyclic endothelin antagonist BE18257B and (c) a family of 36 NMR structures, which demonstrate the well-defined nature of the cyclic peptide backbone.

prominence as a pharmacological lead molecule. Interest in the peptide arose because of its potent renal, pulmonary, and neuroendocrine activities. Endothelin and its isoforms have been implicated in a wide variety of disease states including ischemia, cerebral vasospasm, stroke, renal failure, hypertension, and heart failure. It exerts its pharmacological effect by acting on specific G-protein-coupled receptors. In mammalian species, two receptors, ET_A and ET_B, have been cloned; both are widely distributed in human tissue and are distinguished

by different responses to various ET isoforms.

The NMR-derived three-dimensional structure of ET-1 consists of several distinct regions, including a random-coil N terminus, a β-turn involving residues 5–8, followed by a short helical region and a flexible C-terminal tail. The presence of the flexible tail in solution is not surprising, as may be imagined from the primary sequence shown in Fig. 10. Although solution structures of ET and its analogs determined by NMR have been valuable in defining the gross conformation of these molecules, the flexibility of the tail in solution makes it difficult to extrapolate to the bound state. Indeed, an X-ray structure of ET-1 has quite a different structure for the C-terminal tail than for the random-coil arrangement in solution. The bound conformation may be different again.

There is clearly an advantage in having lead molecules with reduced flexibility, given that their solution conformation will intrinsically provide a better reflection of the bound conformation. In addition, the development of a more rigid drug will reduce unfavorable entropic contributions to binding energy. Indeed, a range of small cyclic peptides that are ET_A- or ET_B-selective antagonists have been discovered and provide valuable leads to the development of potential therapeutics. NMR studies have been instrumental in determining their solution conformations. For example, the rather well-defined solution conformation of the ET_A-selective antagonist BE18257B (shown in Fig. 10) contrasts with the flexibility of the tail region of ET that this peptide is thought to mimic. The discovery and development of these molecules illustrate the principle that cyclic peptides are often more suitable than linear peptides as lead ligands in drug design. In addition to their better defined and less-flexible conformations than those of their linear counterparts, they generally have improved bioavailability and resistance to protease attack.

We shall return to endothelin as a lead in drug design, in relation to a nonpeptidic antagonist. The underlying theme illustrated by the endothelin example is that ligand-based design often proceeds from initial studies of flexible endogenous molecules (particularly peptides) to constrained mimics (e.g. cyclic peptides) and often culminates in the development of nonpeptidic drug leads. NMR assists by defining the structures of the lead and subsequent molecules.

2.1.3 Instrumental Advances and their Impact on Structure Elucidation

Over the last few years, there have been several exciting instrumental developments that promise to dramatically expand the role NMR will play in the drug discovery process. These relate to the combination of NMR with other technologies such as LC and/or MS and the use of NMR to directly monitor reactions carried out on solid-phase resins. The latter promises to indirectly enhance drug discovery programs by improving the monitoring and hence efficiency of solid-phase combinatorial synthesis. Effectively, resin-based syntheses can be monitored at successive stages without the need to cleave intermediate products from the resin.

As already mentioned, the additional sensitivity brought about by cryoprobe technology promises to enhance a wide range of NMR applications, but will be particularly important in natural products-based drug discovery. In many cases, only limited amounts of pure compounds are isolated from natural product extracts and sensitivity has been a major limiting factor on structure elucidation. LC/MS/NMR

systems will greatly improve the efficiency of such analyses by minimizing the need for separate sample-handling steps for the different analytical technologies.

2.2 Conformational Analysis

Usually only 1D or 2D NMR methods are required to determine the solution conformation of bioactive ligands. Useful tools include analysis of chemical shifts, coupling constants, and NOEs. An assumption inherent in the application of such studies to drug design is that the solution conformation will be maintained on binding to the receptor. This is justified in the case of relatively rigid ligands. However, for potentially flexible ligands, the possibility of changes in conformation on binding must be considered, as noted above for the case of endothelin.

Coupling constants and NOEs are the main NMR parameters used in determining the solution conformations of drug leads. NOEs provide information about through-space proximity. Three-bond vicinal-coupling constants are particularly valuable because their dependency on the intervening dihedral angle through the Karplus relationship allows local geometry to be determined. This is illustrated in Fig. 11 for taxol. Although there are several vicinal-coupling constants in this molecule (Fig. 6), only one $^{3}J_{H2H3}$ occurs in a region of the molecule that is expected to be conformationally rigid and thus suitable for conformational determination by use of coupling constants. In taxol and a range of analogs, this coupling is in the range 4–7 Hz, consistent with partially eclipsed dihedral angles of approximately 120–140° for this ring-constrained structure. This is in good agreement with the X-ray structure of a taxol analog, where the angle is 120°. Note that, in general, such a Karplus analysis does not give a unique solution unless several coupling constants sampling the same dihedral angle are present and is reliant on the

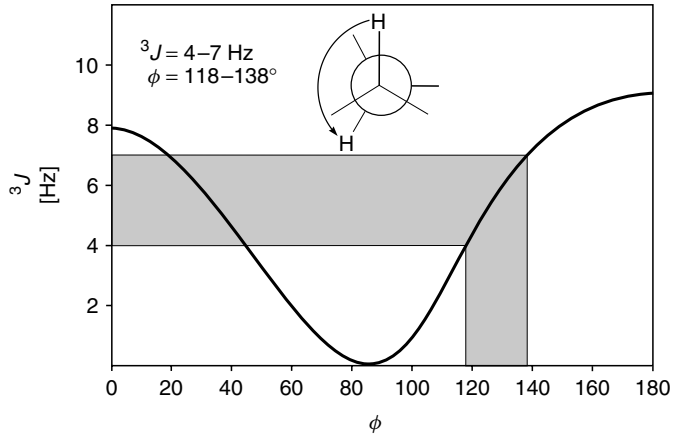

Fig. 11 Illustration of the Karplus relationship between three-bond scalar coupling constants and the dihedral angle of the intervening bond. The relationship is indicated for the phi (Φ) torsion angle of the H2 and H3 protons within the rigid core of taxol and related derivatives. See Fig. 6 for the structure of taxol.

assumption that the molecule exists only in a single conformation in solution. Although it is generally believed that this is the case for the core of taxol, recent relaxation data described in Sect. 2.5 suggest that this conclusion may need to be reexamined.

In addition to studies of the taxol core, there have been a large number of studies of the conformations of the side chains of taxol, and it appears that these are certainly flexible and that the molecule may adopt both extended and folded conformations of the side chains. In a case like this, the observed vicinal-coupling constants are a weighted average of those from the participating conformers.

2.3 Charge State

An advantage of NMR over other structural techniques such as X-ray crystallography is that it has the potential to provide information not only on structure but also on the electronic properties of molecules. Many drug leads contain ionizable groups and a determination of their charge state in solution and/or at the bound site is important in the design of analogs. Simple plots of chemical shifts as a function of pH for nuclei near these ionizable groups provide a convenient way of determining the pK_a value and hence the charge state. This is illustrated for Prialt® in Fig. 12, where it was suspected that one of the ionizable groups in the molecule, Asp^{14}, may be involved in a stabilizing salt–bridge interaction. This was confirmed by noting that the pK_a value for this residue is lowered considerably relative to the usual value for Asp. The β-proton chemical shifts were essentially independent of pH over the range 3–7 (indicating a p$K_a < 3$), whereas those of a control, random-coil peptide, titrated as expected over this range.

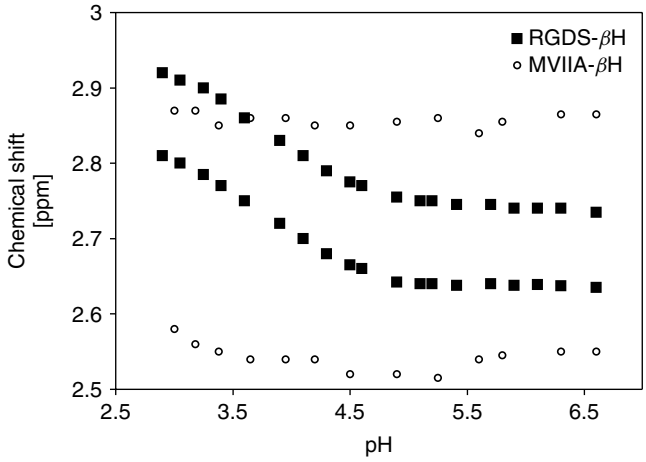

Fig. 12 Chemical-shift changes of the β-protons of Asp14 in MVIIA illustrating the lack of titration of the adjacent carboxyl group, indicating its involvement in salt bridge. By contrast, the shift of a control random-coil peptide varies with an apparent pK_a value of 3.7, as expected for an uncomplexed carboxyl moiety in peptides.

2.4 Tautomeric Equilibria

Tautomerization is a relatively common feature of drug molecules that is amenable to analysis through the use of chemical shifts or coupling constants as probes. This was recently demonstrated in a study of some nonpeptide endothelin analogs. Starting from the modestly active compound (**1**) (Table 5), derived by screening a compound library for ET_A antagonists, the nanomolar inhibitor (**2**) was developed. Further optimization through examination of electronic and structural requirements led to the subnanomolar inhibitor (**3**), which was subsequently put forward for evaluation in a number of preclinical disease models for stroke.

These molecules display keto-enol tautomerization, as illustrated in the keto-enol structures. The open form keto-acid salts and the closed-form butenolides exist in a pH-dependent equilibrium in solution, and at physiological pH, both forms exist. In principle, the biological activity could reside in either or both forms.

The extent of tautomerization was established by evaluation of NMR spectra as a function of pH, from 2.65–9.05. At acidic pH, compound (**2**) exists essentially in the closed butenolide form. Because the pH is slowly raised by addition of NaOD, the spectrum begins to exhibit properties associated with the open form keto acid,

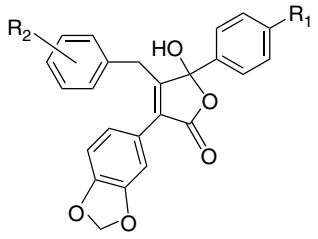
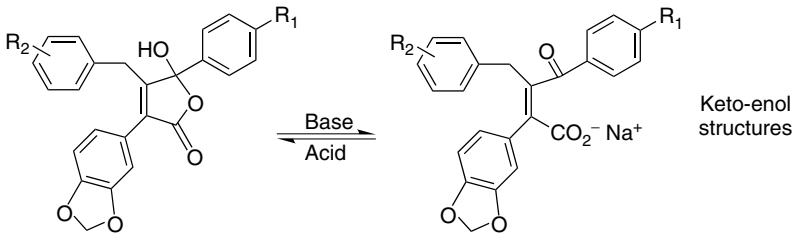
(1999) Butenolide endothelin antagonists with improved aqueous solubility, *J. Med. Chem.* **42**, 2162–2168.



(**1–4**)



and at basic pH the compound is essentially all in the open form. The coupling pattern shown by the benzylic protons is a particularly characteristic marker of the tautomeric process. At acidic pH, the benzylic protons exhibit an AB quartet pattern consistent with the ring-closed structure. As the pH is raised, this pattern coalesces to a singlet, broad at neutral pH and sharp at basic pH, as would be expected with the open form keto-acid structure. After the pH was basic, addition of DCl to acidify the solution caused the spectrum to return to its original appearance, consistent with a reversible tautomerization process.

Identical biological results were obtained with the salt and closed butenolide form in all pharmacological assays, reflecting equilibration at physiological pH. This made it difficult to identify the biologically active form from these experiments alone, although methylation of the OH group in compounds (**1**–**3**) resulted in a loss of activity. Because these analogs cannot tautomerize to form open keto acids, it seems likely that the open form is responsible for activity.

In addition to its impact on the biologically active form, the tautomeric process has profound implications for formulation of drug candidates, as illustrated in some recent development work on compound (**3**). Although it is easy to synthesize and isolate water-soluble salts of the keto acids, once they are placed in aqueous solution the tautomeric equilibrium determines how much of each form is present. Indeed, if the closed butenolide tautomer is sufficiently water insoluble, it can precipitate out of solution and the equilibrium can drive the complete precipitation of the compound. Although (**3**) has good oral activity, its intravenous use is limited by the insolubility of the closed-form butenolide tautomer without the use of a specific and complex buffered formulation. Thus, in recent work, a series of water-soluble butenolides was developed to overcome this limitation for parenteral uses. This culminated in the development of (**4**) (Table 5), currently in preclinical evaluation.

This description of the development of (**4**) provides a good illustration of the fact that the synthesis of an active molecule is not the end of the drug development pathway, and that formulation considerations can be critical. In this case, NMR played a significant role in understanding tautomeric processes that had a direct bearing on solubility and hence formulation.

2.5 Ligand Dynamics: Line-shape and Relaxation Data

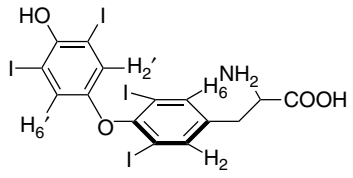
It is increasingly being recognized that the solution molecular dynamics of drugs may have an important role in modulating biological activity. For example, dynamics may influence entropic contributions to the free energy of binding. In general,

the more flexible a ligand is, the more unfavorable will be the loss in entropy on binding, assuming a relatively rigid bound state of the ligand. However, in some cases flexibility of a ligand may be a positive factor. This applies, for example, if a degree of flexibility is required to allow a ligand access to a buried active site, or if activation of a receptor requires a conformational change mediated by ligand binding. Therefore, knowledge of the flexibility of lead molecules is an important supplement to the structural and electronic information available from NMR.

The two major NMR methods for obtaining information on ligand flexibility are line-shape analysis and relaxation measurements (usually ^{13}C or ^{15}N T_1, T_2, or heteronuclear NOE measurements). In general terms, the former is sensitive to motions in the milli- to microsecond timescale and the latter in the nanosecond timescales. To some extent, structure calculations on peptide-based lead molecules can also give an indication of regions of flexibility from an examination of local regions of disorder among a family of calculated structures. Caution must be exercised because other factors can contribute to disorder, although in many cases there is a connection between disorder in a structural ensemble and molecular flexibility.

In an example that illustrates the application of NMR relaxation measurements for studying ligand flexibility, Kessler and colleagues investigated the role of disulfide bonds in the α-amylase inhibitor, tendamistat. This small protein contains two disulfide bonds (C11–C27 and C45–C73) and opening of the latter is known to reduce the melting temperature of the protein (i.e. reduce its stability), but not affect its α-amylase inhibitor function. The latter observation suggests that this disulfide bond may not affect either the structure or the dynamics of the molecule. To investigate this possibility, heteronuclear NOE measurements were used to determine the effect of the selective removal of the single disulfide bond on the dynamics of the molecule. To assess structural changes, chemical-shift differences, intrastrand NOE effects, and protected amide protons were measured for the disulfide-deficient variant C45A/C73A and wild-type tendamistat. Removal of the C45–C73 bond by the C45A/C73A mutation was found to have no influence on the β-barrel structure, apart from very local changes at the mutation sites. ^{13}C and ^{15}N relaxation data showed that the only region of significant internal mobility in either the wild-type or variant protein was at the N terminus. There was little difference in internal flexibility between the two proteins, consistent with their similar α-amylase inhibitory activity. In this case, it appears that the role of the C45/C73 disulfide bond is more related to thermodynamic stability and the secretion efficiency of the protein rather than to limiting its flexibility.

The thyroid hormones, exemplified by thyroxine (**5**), provide an example of the use of both line-shape analysis and NMR relaxation time measurements to give an insight into the internal flexibility, and perhaps the mode of action, of pharmaceutically important molecules. The thyroid hormones act by binding to a nuclear receptor and appear to control receptor function by inducing a conformational change that directs the alignment of functionally critical secondary-structure elements of the receptor. Synthetic thyroxine is widely used for the treatment of thyroid disorders and indeed has been the second most widely prescribed drug in the United States over recent years.



(**5**)

Table 6 shows experimental ^{13}C T_1 and heteronuclear NOE data for thyroxine together with best-fit theoretical values for these parameters based on two different models of the motion of thyroxine in solution. A simple isotropic model, in which the drug is regarded as a rigid body tumbling in solution, is clearly unable to simultaneously fit the T_1 and NOE data, whereas the two-state jump model, which incorporates a degree of internal mobility based on rapid flipping between conformational states, is better able to account for the experimental data. Although it is difficult to precisely define the nature of the internal motion, it is clear that rapid (nanosecond) internal motion is present, and this appears to involve small-amplitude torsions about the aromatic ring axes. The correlation time for overall tumbling of thyroxine was deduced to be approximately 0.35 ns, with the internal motion approximately 30-fold faster.

Studies of the ^1H-NMR spectrum of thyroxine as a function of temperature had earlier demonstrated the presence of additional larger amplitude, but slower ring flips. At low temperature, two signals were seen for the H2′ and H6′ protons. These signals broadened with increasing temperature, then coalesced and sharpened as the temperature was further increased. This was attributed to exchange of the environments of the two protons brought about by 180° rotation of the ''outer'' ring of thyroxine. Substitution of the observed coalescence temperature (T_c) and the chemical-shift difference of the two signals at low temperature ($\delta\nu$) allowed the free energy of activation for this slow ring flip process to be established from Eq. 1

$$\Delta G^{\neq} = 19.14\ T_c \left[9.97 + \log\left(\frac{T_c}{\delta\nu}\right)\right] \quad (1)$$

The derived barriers for several thyroid hormones are in the range 36–38 kJ mol^{-1}, which corresponds to large-amplitude ring flips on the milli- to microsecond timescale. From a combination of the relaxation data and the

dynamic line-shape analysis data, it was possible to propose a unified model that accounts for both the fast and slow internal motions, as summarized in Fig. 13.

In this model, both aromatic rings of the thyroid hormones jump rapidly between two energetically equivalent conformations on a nanosecond timescale (a ↔ b and c ↔ d in Fig. 13). The half-angle of the jump varies, depending on the solvent, corresponding to an average displacement of about 90° between the two extreme jump positions. These separate states are not detectable on the chemical-shift timescale but lead to an average proximal environment for Ha and an average distal environment for Hb (attributed to rapid interchange between a and b in Fig. 13), which are seen in the low temperature spectra. However, these fast motions are detected by relaxation studies. Although the rate of this motion is rapid, its amplitude is not sufficient to average the environment of proximal and distal protons. Occasionally (about once every 1000 jumps), the outer ring jumps further

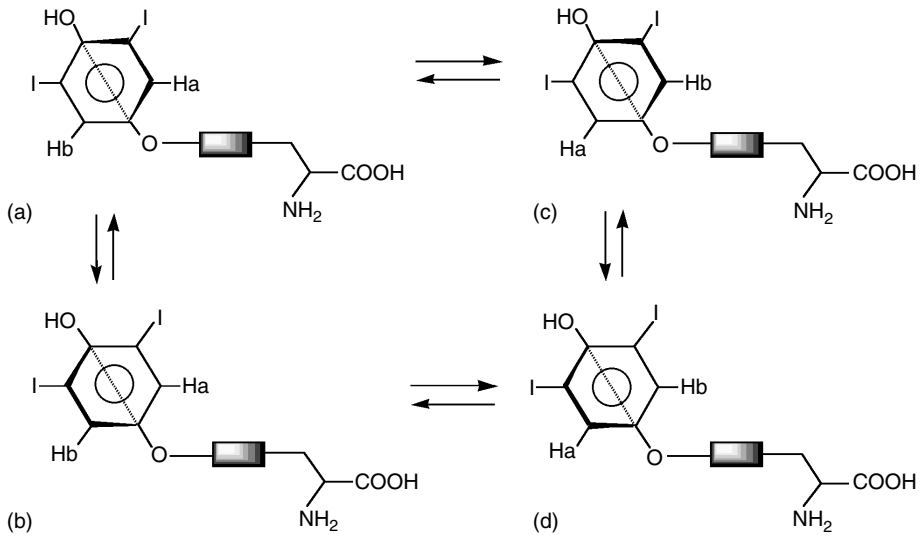

Fig. 13 Schematic illustrations of motions of the outer ring of thyroxine. The dotted line through the outer ring shows the jump axis about which the ring rotates. (a) Ha is shown in the proximal position and is closer to the viewer than Hb because the torsion angle phi $(\Phi)'$ is greater than 0°. This conformation corresponds to one of the two states of the two-state jump model and agrees with the "twist" of the outer ring observed in the crystal structure.
(b) Rotation about the dotted line through the center of the outer ring moves Ha away from the viewer and brings Hb toward the viewer. This corresponds to the second state of the outer ring in the two-state jump model. (c) Hb is now in the proximal position and closer to the viewer than Ha. (d) Hb is in the proximal position and is now further from the viewer than Ha. Transition from a to b and from c to d involves small-amplitude jumps on the nanosecond timescale and is detected by NMR relaxation measurements. Although not illustrated in the figure, the inner ring also exhibits this type of motion. Transitions a to c and b to d result in 180° flips of the outer ring and exchange of the environments of Ha and Hb. This ring flip occurs on a microsecond timescale and is detected by variable-temperature line-shape studies.
(Reprinted with permission from the American Chemical Society from Duggan, B.M., Craik, D.J. (1996) *J. Med. Chem.* **39**, 4007.)

than the nominal 90° range, exchanging the environments of the proximal and distal protons (a ↔ c and b ↔ d in Fig. 13). Although the actual rate of an individual ring flip is rapid, the effective rate of the process is on the microsecond timescale, because on average a large number of small-amplitude jumps occur for every large-amplitude ring flip. It is the exchanging of proximal and distal protons on the microsecond timescale that is detected by the variable-temperature lineshape studies.

The fact that thyroxine is apparently able to so freely move over a moderately large region of conformational space has implications for receptor binding. The crystal structure of the thyroid receptor ligand-binding domain complexed with the thyroid agonist 3,5-dimethyl-3′-isopropylthyronine shows that the thyroid hormones bind at the center of the hydrophobic core of the ligand-binding domain and may play a structural role in the conformational changes that activate the receptor. The structures of the retinoid-X receptor ligand-binding domain and the retinoic acid–retinoic acid receptor ligand-binding domain complex indicate that significant conformational changes accompany ligand binding in those cases. The conformational flexibility exhibited by the thyroid hormones may also be required for binding. It has been suggested that the rapid ''wiggling'' of the aromatic rings could enable the hormone to work its way to the center of the ligand-binding domain as the protein reorders itself about the ligand and may in fact trigger receptor conformational changes.

As briefly mentioned earlier, taxol provides another example where relaxation time measurements provide an insight into dynamics processes. Although it is generally thought that the taxane core is rigid, ^{13}C relaxation data suggest that a degree of flexibility (on the nanosecond timescale) may be present and may vary for different taxol analogs. In particular, it appears that the removal of certain side chains may introduce additional flexibility into the core region that would not easily be predicted on the basis of a simple inspection of the structure.

Another example of the application of line-shape analysis to ligand dynamics is described in Sect. 3.2 for the drug trimetrexate when bound to dihydrofolate reductase (DHFR). From that example and earlier studies on DHFR, it is clear that the techniques described earlier can equally be applied to ligands when bound to their receptor. In some cases, significant but highly specific mobility appears to be present at the bound site.

2.6 Pharmocophore Modeling: Conformations of a Set of Ligands

Determination of the conformations of a range of ligands all of which act at the same receptor site can provide significantly more information than just a single ligand structure. With a sufficiently broad range of ligands, it is often possible to generate a pharmocophore model of the receptor site, deduced on the basis of the conserved structural features and the conformations of the ligands. This has been done recently, for example, for the ω-conotoxins, the broad class of conotoxins to which Prialt® belongs. From structural studies of a range of ω-conotoxins and from literature data on various mutants with altered binding affinities, it was determined that only a localized region of the surface of these molecules is involved in receptor binding. This allowed a pharmocophore model of

putative receptor-binding pockets to be developed.

The advantage of such a pharmocophore model is that smaller, nonpeptide molecules that might have improved stability and bioavailability over their peptidic counterparts can, in principle, be designed. The NMR approach used in such pharmocophore modeling often involves a combination of many of the techniques already described. By determining information about structure and electronic properties for a range of different ligands, all acting at the same receptor site, it is often possible to infer information about the binding site, even if direct structural studies of this site are not possible.

2.7 Limitations of Analog-based Design

Although a determination of the structure of bioactive molecules is of key importance, there are distinct limitations on the use of solution structures for drug design. In particular, unless the molecule is rigid there is no certainty that the solution conformation is the same as the bioactive bound conformation. For this reason, there has been a shift over recent years to approaches in which information about the bound state is obtained. The other approach has been to probe the bound conformation by making a range of constrained analogs of a flexible lead molecule, as illustrated earlier for endothelin.

The most direct way of determining the conformation of a drug lead is to determine the full three-dimensional structure of its receptor complex. This has now been achieved in a significant number of cases but represents a substantial undertaking, as described in later sections of this chapter. A simpler approach that has also been applied is to use transferred nuclear Overhauser effect (TrNOE) methods, as described in the following sections. This approach fits at the interface of ligand-based design and receptor-based design. It fits with the former because no knowledge of the receptor structure is required, but it also fits with the latter because it requires the macromolecule of interest to be included in the mixture to be analyzed. It is appropriate therefore to introduce the topic here but also to discuss it further in Sect. 3.

2.8 Conformation of Bound Ligands: Transferred NOEs

In ligand-based drug design, it is not necessary to know the structure of the receptor, or even the location of the binding site, although the conformation of the ligand bound to the receptor is crucial. It is clearly better if this can be measured directly rather than be inferred from the conformation of the free ligand. In certain circumstances this information on the bound conformation can be obtained from the TrNOE technique. This method takes advantage of the fact that NOEs build up more rapidly in a ligand–macromolecule complex than they do in free ligand, and given appropriate exchange conditions for a mixture of ligand and macromolecule (typically satisfied for $K_D \geq 10^{-7}\ M^{-1}$), then signals from a free ligand may be used to determine the bound conformation.

Because it is not necessary to monitor signals from the macromolecule in this technique, as it is usually present in substoichiometric amounts, thus requiring only minimal amounts of what is sometimes the more expensive component of ligand–macromolecule complexes. In addition, the molecular weight restrictions inherent in full 3D-structure

determinations of complexes are ameliorated and the conformations of ligands bound to very large macromolecules may be determined. For example, the technique was recently used to determine the structure of an antibiotic bound to the ribosome and a range of other applications including enzyme–substrate, protein–carbohydrate, and protein–peptide interactions have been reported.

In addition to its application as a tool for determining bound conformations of ligands, the TrNOE method has also been used recently as a screening aid for the identification of ligands from mixtures that bind to a protein of interest. This application is addressed in more detail later in this chapter.

3 Receptor-based Design

Receptor-based design refers to the process of determining the three-dimensional structure of a macromolecular target and using this information to design ligands to interact with it. In general, there have been few cases where the structure of a macromolecule or receptor alone has been successfully used to design, *de novo*, a ligand to interact with that receptor. However, such an approach is likely to become more common with improved computer-based approaches to molecular design in the future. Currently, the most common approach is to study a ligand–macromolecule complex and to initiate the design process based on the interaction of the lead ligand with the macromolecule.

Although the structure of the macromolecule alone is of less interest than that of the complex, in many cases a determination of the structure of the complex follows from earlier studies on the unbound macromolecule. It is thus useful to describe the approaches to structure determination of macromolecular targets. This is followed by a discussion of the dynamic aspects of protein structures in Sect. 3.1, before addressing the main topic of macromolecule–ligand interactions in Sect. 3.2.

3.1 Macromolecular Structure Determination

The two major techniques for determining three-dimensional structures of proteins or nucleic acids are X-ray crystallography and NMR spectroscopy. NMR has been used to determine the structures of proteins for only 20 years, with the first NMR structure determination being made in 1985. NMR has a number of advantages over X-ray crystallography, including the fact that the requirement that the protein needs to be crystallized is avoided, and that the dynamic information available from NMR studies complements the structural information. A major disadvantage of NMR spectroscopy, though, is that it is currently limited to the determination of structures of <35 kDa. With the development of new NMR techniques, such as TROSY, this seems certain to increase significantly over the coming years, although the fact remains that among all structures currently deposited in the protein database the average size of NMR structures is about 8 kDa, substantially smaller than the average size of protein structures determined by X-ray crystallography. Despite this limitation, NMR has made major inroads into the macromolecular structure determination process, and currently approximately one-fifth of all new structures deposited in the protein database have been determined by NMR spectroscopy.

3.1.1 Overview of Approach

The basis for structure determination by NMR is that, by determining a large number of distance restraints between pairs of protons, it is possible to reconstruct a three-dimensional image of the molecule. These distance restraints are derived primarily from NOE measurements, which detect distances up to about 5 ´Å. Over recent years, such distance restraints have been supplemented by a range of other restraints, including dihedral angle restraints derived from coupling constant measurements and orientation restraints derived from residual dipolar couplings. These restraints are input into a simulated annealing algorithm, which is used to calculate a family of structures consistent with the restraints.

NMR is unique in that it can provide detailed and specific information on molecular dynamics in addition to structural information. The use of relaxation time measurements allows the relative mobility of individual atomic positions within a macromolecule to be determined. The dynamic information obtained includes not only the rates or frequencies of internal motions but also their amplitudes. Such amplitudes are often expressed by order parameters. Not surprisingly, it is observed in many cases that the termini of proteins are more flexible than internal regions. More interestingly, NMR has provided a number of examples where internal loops in proteins have been shown to have dynamics that may be associated with their function. A good example of this is HIV protease, where NMR studies have identified lowered order parameters in the flap region of the molecule, which may reflect flexibility to allow entry of substrates or inhibitors into the active site.

In summary, a major strength of NMR is that a global picture not only of the structure but also of the dynamics of the macromolecular target is obtained. Further, NMR provides information on ionization states of titratable groups and other electronic features within macromolecules, which may have an impact on ligand binding and function.

3.1.2 Sample Requirements and Assignment Protocols

Structure determination by NMR typically requires 500 µL of a 1–2 mM solution of the protein of interest. It is important that the macromolecule does not aggregate because this causes spectral broadening and may preclude assignment. The sample should preferably be stable in solution over the extended period of time required to collect the range of NMR experiments needed for assignment and structure determination. Individual experiments may last from a few hours to several days, with several weeks of data acquisition required for studies of larger proteins.

The particular set of NMR experiments required for NMR structure determination depends on the size of the protein. For smaller proteins ($\leq$7 kDa) it is usually possible to determine the structures, mainly using 2D NMR, without the need for isotopic labeling, by use of procedures described in detail earlier for Prialt®. For proteins in the range 7–14 kDa, ^{15}N-labeling and a combination of 2D/3D NMR experiments is usually sufficient, whereas for larger proteins ^{13}C/^{15}N labeling and 3D or 4D NMR is more or less mandatory. For proteins at the top end of the currently accessible range (25–35 kDa), there are additional advantages associated with partial deuteration of the protein.

3.1.3 Recent Developments

A number of recently developed methods offer the potential for improving the quality of NMR structures and for increasing the size of proteins that can be examined. In particular, the use of residual dipolar couplings and of anisotropic contributions to relaxation provide new kinds of restraints that promise to lead to more accurate NMR structures. As already mentioned, the TROSY method exploits relaxation phenomena to produce spectra with narrow lines and promises to significantly expand the size of protein targets that can be examined by NMR, from the current limit of about 35 kDa to perhaps >100 kDa.

Another development that is likely to have a significant impact is the increasing number of structural genomics programs being developed. The demands arising from such programs will no doubt stimulate new methods for the large-scale production of labeled proteins, and for speeding up the rate of structure determination by both NMR and crystallography.

3.1.4 Dynamics

Proteins exhibit a range of internal motions, from the millisecond to nanosecond timescale, and a full understanding of how small drugs might interact with such a ''moving target'' requires more than just the time-averaged macromolecular structure. Thus, over recent years much effort has been directed toward defining motions within proteins.

The most commonly applied approach has been to use ^{13}C or ^{15}N relaxation parameters such as T_1, T_2, and the heteronuclear NOE to derive correlation times for overall motion, together with rates and amplitudes of internal motions. Although the precise interpretation of the NMR relaxation data in terms of motional parameters remains dependent on the appropriateness of the motional model chosen, the results from many studies on the dynamics of proteins are sufficiently clear to confirm that nanosecond timescale motions in proteins are common. The functional significance of motions on the nanosecond timescale remains unclear and so far there have been few cases where significant differences in motions on this timescale between ligand-free and ligand-bound forms of proteins have been measured. It will be interesting to assess the functional significance of such motions as more data become available. However, slower motions have been correlated with function in a number of proteins, with a good example being HIV protease, described in more detail in Sect. 3.2.4.5

3.1.5 Nucleic Acid Structures

Most of the discussion on macromolecular targets so far has focused on proteins. DNA represents another valuable target in drug design. Most studies in which DNA is the target are done using short model oligonucleotides to mimic the binding region of DNA. The regular repeating nature of DNA structures makes this a more successful approach than similar attempts to dissect out binding regions of receptor proteins, where often the whole protein must be present to maintain a viable binding site. Similar comments apply for RNA, where improvements in synthetic methods have led to an increasing number of structure determinations over recent years. The principles involved in structure determination of nucleic acid targets are similar to those of proteins, but in practice nucleic acid structures are somewhat more difficult to solve.

3.1.6 Challenges for the Future: Membrane-bound Proteins

The majority of targets for currently known drugs are membrane-bound receptors, yet this represents the class of proteins for which least structural information is known. Membrane proteins are notoriously difficult to characterize at a structural level because they are difficult to crystallize, thus inhibiting X-ray crystallographic studies, and are both too large and too difficult to reconstitute in suitable media for NMR studies. Nevertheless, solid-state NMR methods are beginning to show promise that eventually such targets may be structurally characterized.

3.2 Macromolecule–Ligand Interactions

Macromolecule–ligand interactions are integral to a wide range of biological processes, including hormone, neurotransmitter or drug binding, antigen recognition, and enzyme–substrate interactions. Fundamental to each of these interactions is the recognition by a ligand of a unique binding site on the macromolecule. Through an understanding of the specific interactions involved it may be possible to design or discover analogous ligands with altered binding properties that might inhibit the biochemical function of the macromolecule in a highly specific manner. The study of macromolecule–ligand interactions thus forms the cornerstone of most structure-based drug design applications. The macromolecule of interest may be a protein or a nucleic acid, although the majority of drug design applications have focused on protein–ligand interactions. For this reason, we will refer mainly to protein–ligand interactions in the following discussion, but will also include some examples of drug–DNA interactions.

3.2.1 Overview

There are several important aspects of macromolecule–ligand interactions, which have a bearing on structure-based design. The simplest question that might be asked is ''what is the strength of the binding interaction?'' whereas the most detailed task would be to precisely define the atomic coordinates of the complete protein–ligand complex. In between these extremes there are many other questions that are important to the drug design process; these include questions about the binding stoichiometry and kinetics, the conformation of the bound ligand, and about the nature of functional group interactions between the protein and bound ligand. These and other important questions were introduced briefly in Table 3 and are examined in more detail later in this section. Before doing this it is first necessary to consider NMR timescales, because the ability of NMR methods to answer questions about macromolecule–ligand complexes depend critically on the kinetics of the binding interaction. Section 3.2.2 thus describes how various NMR parameters depend on binding kinetics and, in particular, how fast- and slow-exchange conditions affect the interpretation of NMR data.

Having identified the exchange regime, the task then becomes to decide which NMR parameters can be used to answer the questions posed above about the complex. Many of the NMR parameters that were described earlier for deriving information about ligands are also applicable to studies of complexes. These include chemical shifts, NOEs, and relaxation parameters. However, the presence of two interacting partners means that there are some differences in the way such parameters are measured, and this has led to the development of several techniques that are particularly important for the

study of macromolecule–ligand interactions, including chemical-shift mapping, isotope editing, and various NMR titrations. Section 3.2.3 describes these techniques. Finally, illustrative examples of the application of these techniques to specific drug design problems are given in Sect. 3.2.4.

3.2.2 Influence of Kinetics and NMR Timescales

Macromolecule–ligand interactions are characterized by an equilibrium reaction that potentially has a wide range of affinities and rates:

$$M + L \longleftrightarrow ML$$

The rate constant for the forward reaction is referred to as the *on rate* (k_{on}), whereas dissociation of the complex is characterized by the reverse rate constant, k_{off}. The equilibrium constant for this interaction, represented in terms of the dissociation constant of the complex K_D, reflects a balance of the on and off rates, as shown in Eq. 2:

$$K_D = \frac{[M][L]}{[ML]} = \frac{k_{off}}{k_{on}} \qquad (2)$$

For many protein–ligand interactions, k_{on} is of the order of 10^8 M^{-1} s^{-1}, and is typically quite similar for different ligands. The observation that K_D values may vary over a wide range, typically from millimolar to nanomolar (i.e. $K_D = 10^{-3} - 10^{-9}$ M) for cases of interest, is a reflection of a variation in k_{off} for different ligands. Consideration of the k_{on} value above and the range of K_D values noted suggests a range in k_{off} from 10^{-1} to 10^5 s^{-1}. The lifetime of the bound complex ($\tau_{ML} = 1/k_{off}$) may thus vary from much less than a millisecond to tens of seconds (10^{-5} to 10 s based on the above off rates). The exchange rate for the second-order binding process is given by:

$$k = \frac{1}{\tau} = \frac{1}{\tau_{ML}} + \frac{1}{\tau_L} = k_{off}\left(1 + \frac{p_{ML}}{p_L}\right) \qquad (3)$$

where p_{ML} and p_L are the mole fractions of bound and free ligand, respectively.

The appearance of an NMR spectrum of a protein–ligand complex is dependent on the rate of chemical interchange between free and bound states. In particular, the effects of exchange on an individual NMR parameter (e.g. chemical shift, coupling constant, or relaxation rate) depend on the relative magnitude of the exchange rate and the difference in the NMR parameter between the two states. The cases where the rate of interchange is greater than, about equal to, or less than, the parameter difference are respectively referred to as *fast*, *intermediate*, and *slow* exchange, as indicated in Table 7.

Table 7 shows that the changes in chemical shifts on ligand binding (for signals either from the ligand or from the macromolecule) are in general greater than those for coupling constants or relaxation rates. Given that 100 s^{-1} might represent a typical exchange rate between free and bound states, it is clear that individual NMR signals may be found in either slow, fast, or intermediate exchange on the chemical-shift timescale, but it is more likely that couplings or relaxation parameters will be in fast exchange. Thus, in most cases where the term ''NMR timescale'' is used in the literature, it refers to the chemical-shift timescale. The table also emphasizes that there are two types of signals that can be monitored, those from the ligand and those from the macromolecule. In general, the typical magnitude of changes to chemical shifts or couplings of either

Tab. 7 NMR parameters and their changes on binding.

Parameter	*Difference*	*Typical magnitude*[a]
Chemical shift	$\nu_L - \nu_{ML}$	0–1000 s^{-1}
	$\nu_M - \nu_{ML}$	0–500 s^{-1}
Coupling constant	$J_L - J_{ML}$	0–12 s^{-1}
	$J_M - J_{ML}$	0–12 s^{-1}
Relaxation rate[b]	$1/T_L - 1/T_{ML}$	0–50 s^{-1} (for T_1, larger for T_2)
	$1/T_M - 1/T_{ML}$	0–10 s^{-1}

[a] Ranges are approximate only and larger effects may be seen in some cases.
[b] $1/T$ refers to either $1/T_1$ or $1/T_2$.

type of signal on binding are similar, although the changes to ligand signals may be larger than those from the macromolecule. However, changes to relaxation parameters for signals from ligands are much more likely to be greater than those for protein signals. This reflects the sensitivity of relaxation parameters to molecular mobility: a ligand undergoes a greater relative change in mobility on binding than does a protein, given that the relative increase in molecular weight in the complex is much greater for the ligand than for the protein.

The exchange regime (slow, intermediate, or fast) determines how a spectrum of a protein–ligand mixture changes during a titration, or as a function of temperature. Figure 14 schematically illustrates the various exchange regimes for macromolecule–ligand binding interactions. Slow exchange, corresponding to tight binding, is potentially the most useful regime, given that much detailed information on the nature of a complex can be deduced in this case. Nevertheless, fast exchange also allows valuable kinetic and thermodynamic parameters to be derived. The analysis is more complex for intermediate exchange and few quantitative studies are attempted for this situation.

3.2.2.1 **Slow exchange.** This situation applies when the rate of exchange is much slower than the difference in chemical shifts between the two states (i.e. $k \ll \nu B - \nu F$), where we now change to a nomenclature using subscripts to refer to the bound (B) and free (F) states. It should be understood that the signals may be derived from either ligand or macromolecule, so although B is always related to the ML complex, F might refer to either free ligand (L) or free macromolecule (M). In this situation, separate peaks are potentially observable for both free and bound states at their respective chemical shifts. Whether such signals are *actually* observed depends on the mole ratio of the individual species in a titration, and on the signals not being obscured by overlap or broadening.

Addition of a ligand to a solution of a protein results in the appearance of new signals attributed to bound protein resonances, with a concurrent decrease in the intensity of the free protein resonances, reflecting the decreased proportion of free protein during the titration. Once a stoichiometric mole ratio is achieved (usually 1 : 1, but sometimes 2 : 1 or higher if multiple binding sites are present on the protein), peaks from free ligand appear

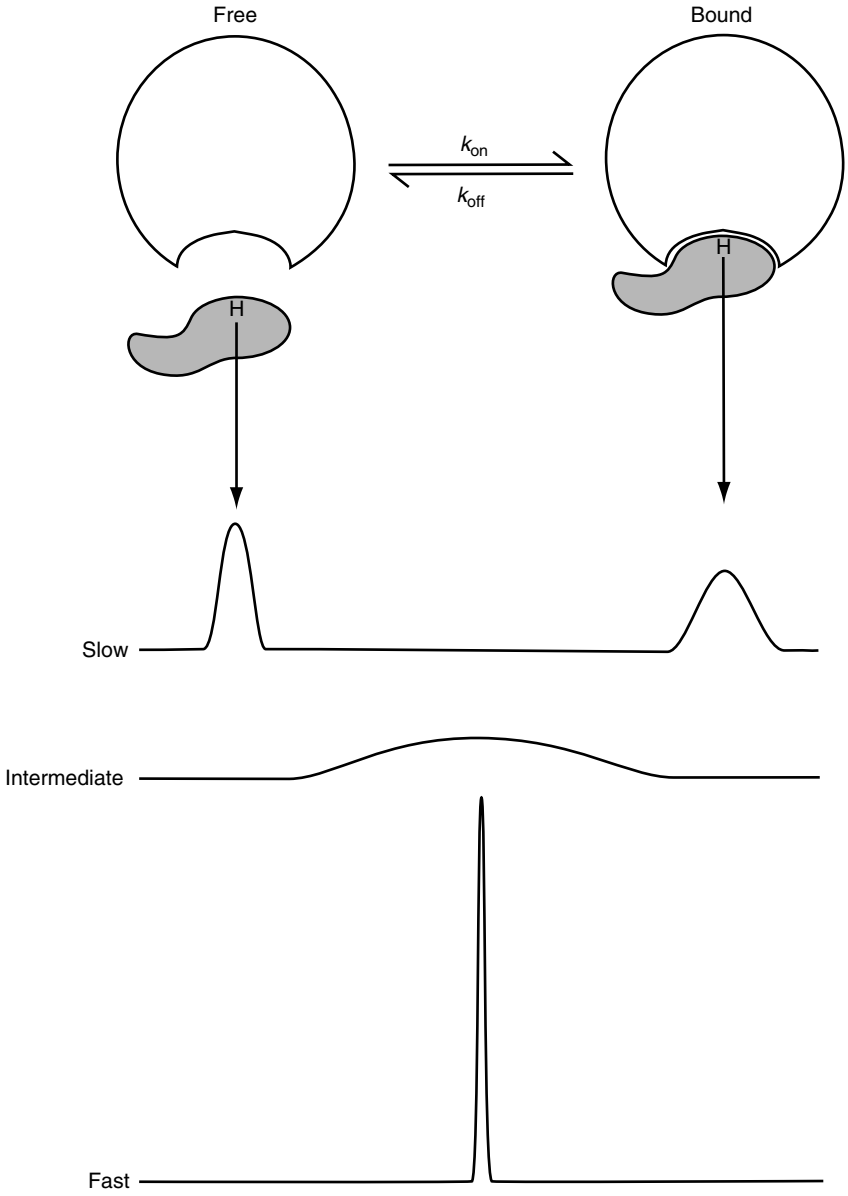

Fig. 14 Schematic illustration of the effects of slow, intermediate, and fast exchange on the appearance of peaks in NMR spectra of macromolecule–ligand complexes. In the slow-exchange case, separate peaks are seen for free and bound forms. Note the broader peak for the bound ligand because it now adopts the correlation time of the macromolecule. In the fast-exchange case, only an averaged peak is observed.

with increasing intensity as the excess of free ligand increases.

From such a titration it is possible to determine the stoichiometry of the complex, together with the chemical shifts of the bound states of the ligand and protein. In 1D NMR spectra, overlap of peaks makes it difficult to monitor more than a few resonances from either species, and such studies are most readily done when there is a well-resolved signal on one of the interacting species. Selective isotope labels have been used in the past for such studies, but it is now more common to use uniform ^{15}N- or ^{13}C-labeling of the protein and detect the chemical shifts in 2D HSQC spectra. It is often more difficult to label the ligand, but in some cases, the presence of rare nuclei such as ^{19}F can be used to advantage. A good example is the binding of the inhibitor 4-fluorobenzenesulfonamide to the enzyme carbonic anhydrase. Figure 15 shows ^{19}F spectra of the enzyme inhibitor complex at various mole ratios. The broadened peak for the bound ligand has a chemical shift of approximately 6 ppm and is in slow exchange with the peak from free ligand at 0 ppm. The stoichiometry of the complex in this case is 2 : 1, so that no signal from free ligand is visible until more than 2 mol of inhibitor are present. Addition of increasing amounts of ligand results in an increase in the free ligand signal, but no change in the bound ligand signal.

Determination of the binding constant from slow exchange spectra is not usually attempted. Generally, for slow-exchange conditions to exist in the first place, the binding is required to be submicromolar in affinity and non-NMR methods are more suitable for determining affinities in these cases. NMR studies are done at millimolar concentrations, making it difficult to determine K_D with any accuracy for tight binding systems.

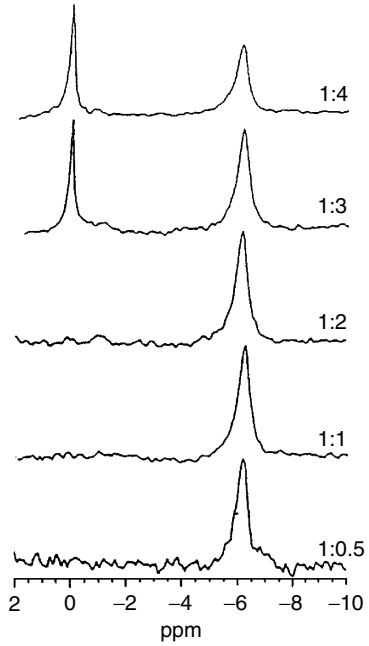

Fig. 15 ^{19}F NMR spectra at 282 MHz of the 4-fluorobenzenesulfonamide-carbonic-anhydrase-1 system at various ratios of enzyme to inhibitor, as indicated on the traces. The peak at ~6 ppm is caused by bound inhibitor. The enzyme concentration was 1 mM at pH 7.2 in D_2O at 25 °C. (Reprinted with permission from the American Chemical Society from Dugad, L., Gerig, J.T. (1988) *Biochemistry*, **27**, 4310.)

In principle, kinetic information on the complex can be obtained from slow-exchange spectra, as seen from the expressions for T_2 for free and bound ligand signals:

$$\frac{1}{T_{2F,obs}} = \frac{1}{T_{2F}} + k_{off}\frac{p_B}{p_F} \quad (4)$$

$$\frac{1}{T_{2B,obs}} = \frac{1}{T_{2B}} + k_{off} \quad (5)$$

Because the linewidth of a peak is related to T_2 by

$$LW = \frac{1}{\pi T_2} \quad (6)$$

then measurements of linewidth during a titration can be used to derive k_{off}. Equations 4 and 5 show that, although the signal from bound ligand is independent of concentration, that of the free ligand decreases in linewidth as more ligand is added. A plot of linewidth versus ligand/macromolecule mole ratio allows k_{off} to be determined.

Although the determination of off rates is of significance in assessing the stability of the complex, the major interest in more recent studies of complexes in the slow-exchange limit has centered on determining the complete geometry of the complex through the use of intra- and intermolecular NOEs. A recent, but already classic, example of this approach is illustrated by the binding of immunosuppressant peptides such as cyclosporin and FK506 to their receptors. These types of examples are discussed in more detail in Sect. 3.2.4.2.

3.2.2.2 **Fast exchange.** When exchange between free and bound states is very fast, observed NMR parameters are a simple weighted average of those from the two contributing states, illustrated by Eq. 7 for chemical shifts and Eq. 8 for linewidths

$$\nu_{obs} = p_F\nu_F + p_B\nu_B \quad (7)$$

$$\frac{1}{T_{2,obs}} = \frac{p_F}{T_{2,F}} + \frac{p_B}{T_{2,B}} \quad (8)$$

These equations show that, in the fast-exchange limit, addition of a ligand to a protein solution will cause a progressive change in chemical shift. Signals from the protein initially reflect the free state, but as ligand is added, the population of bound protein increases, and the observed signals move toward those of the bound state. Similarly, when ligand signals are first detected, they predominantly reflect the bound state, but with increasing amounts of ligand they move toward the chemical shift of the free state. By regression analysis to Eq. 7, taking into account the dependency of the mole fractions on K_D by the standard quadratic binding equation, it is possible to obtain estimates of both K_D and the bound shift. The procedure works best for rather weakly binding ligands (e.g. millimolar dissociation constants).

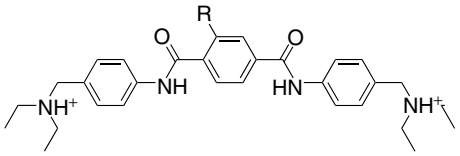
When exchange is somewhat slower, but still within the fast-exchange limit, there is an exchange contribution to linewidth, as shown in Eq. 9:

$$\frac{1}{T_{2,obs}} = \frac{p_F}{T_{2,F}} + \frac{p_B}{T_{2,B}} + \left\{\frac{p_B p_F^2\, 4\pi^2(\nu_B - \nu_F)^2}{k_{off}}\right\} \quad (9)$$

In this case, a maximum in the broadening of ligand or protein peaks occurs during the titration at a mole ratio of approximately 0.3, as illustrated below.

The spectral changes that occur in the fast-exchange regime can conveniently be illustrated by studies on the binding of a series of terephthalamide ligands to an

oligonucleotide model of DNA. The ligands, referred to as L(NO_2), L(NH_2), and L(Gly) (**6**–**8**), were synthesized as precursors for potential anticancer agents. To establish whether they bind in the minor groove of AT-rich DNA, a series of NMR titration experiments was undertaken



(**6**) L(NH_2) R = NH_2
(**7**) L(NO_2) R = NO_2
(**8**) L(Gly) R = $NHCOCH_2NH_2$

Figure 16 shows an expansion of the aliphatic region of a series of ^{1}H-NMR spectra of 0.5 mM of the oligonucleotide d(GGTAATTACC)$_2$, to which increasing amounts of L(NH_2) were added, of which the spectra cover mole ratios of ligand to DNA duplex ranging from 0 : 1 to 2.6 : 1. Although the spectra are complicated by overlap in some regions, it is clear that addition of the ligand causes significant changes to the DNA peaks. A typical example is seen for the T6 methyl peak, for which addition of ligand causes both an upfield shift and broadening of the peak at certain stages of the titration. The chemical shift moves monotonically with ligand concentration up to a mole ratio of 1 : 1 and then reaches a plateau, remaining constant as larger amounts of ligand are added. Broadening of the peak reaches a maximum at a ligand:DNA mole ratio of approximately 0.3. Both observations are consistent with there being moderately fast exchange on the chemical-shift timescale between the free and ligand-bound forms of the DNA in solution. In this case, the observed spectral peaks reflect neither the free nor the bound form of DNA, but are averaged signals.

Ligand peaks are also in fast exchange, as seen with the L(NH_2) methyl peak, which first appears at a ligand:DNA ratio of 1.36 : 1 as a shoulder on the overlapped T3 and T7 methyl peaks at approximately 1.27 ppm. This peak is not initially visible in spectra at low ligand:DNA mole ratios because of the small population of bound species and the overlapping DNA peaks. It moves upfield with increasing ligand concentration and, again, represents an averaged peak intermediate in chemical shift between free and bound forms, reflecting fast-exchange kinetics. Eventually, the chemical shift of this signal approaches that of the free ligand at 1.1 ppm, as measured in a separate experiment with a solution of ligand alone.

In fast-exchange cases such as this, it is possible to obtain an estimate of the dissociation constant for the complex (K_D) and the bound chemical shift (ν_B) of DNA resonances by fitting the observed chemical-shift changes as a function of ligand concentration to Eq. 7. The parameters that best fit the experimental data for the T6 methyl peak were $K_D = 1.2 \times 10^{-6}$ M and $(\nu_B - \nu_F) = 46$ Hz. To further define the thermodynamic constants associated with binding, the linewidth data were also quantitatively examined by use of Eqs. 6 and 9. In the case of moderately fast exchange, a maximum linewidth is predicted at a ligand:DNA mole ratio of 0.33, and this was indeed observed. Derived binding parameters were $K_D \leq 1.0 \times 10^{-6}$ M, $k_{off} \approx 250\ s^{-1}$, $(\nu_B - \nu_F) = 49$ Hz, and $LW_B = 12$ Hz, consistent with the values derived from the analysis of chemical shifts. Subsequent studies with the related ligand L(NO_2) showed similar binding to L(NH_2). However, a third ligand, L(Gly), was found to bind somewhat more tightly,

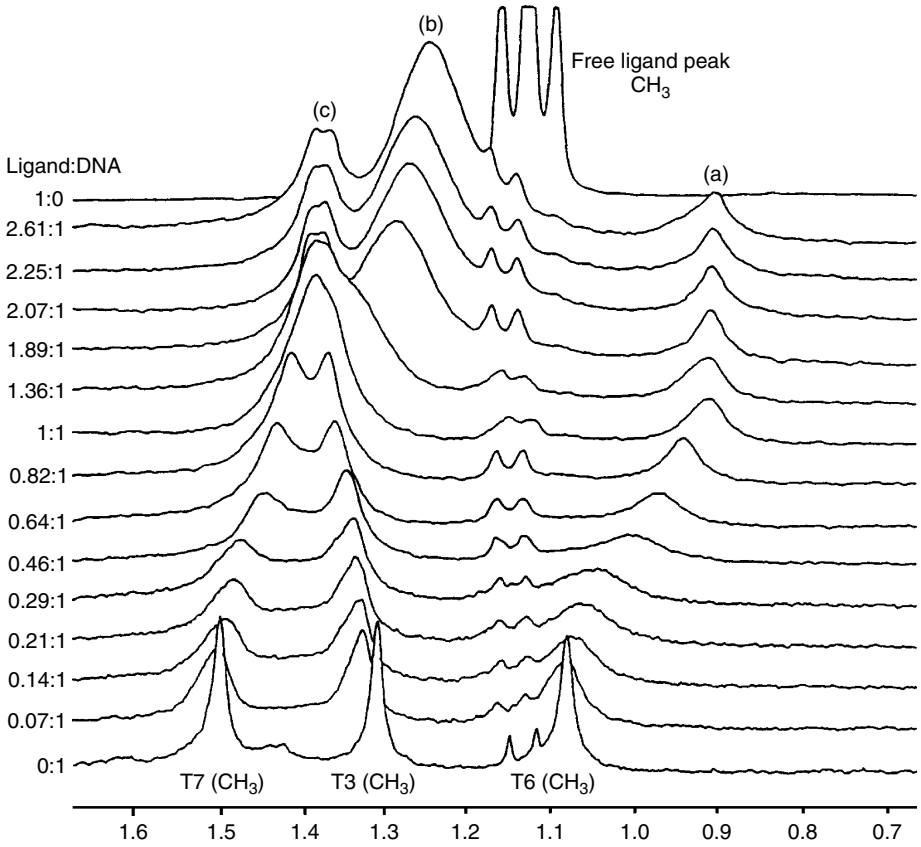


Fig. 16 Expanded regions from 300-MHz ^{1}H-NMR spectra for complexes between L(NH_2) and d(GGTAATTACC)$_2$ recorded at 10 °C. The two small peaks at 1.12 and 1.14 ppm arise from an impurity. Increasing ligand concentration causes an upfield shift of the T6 methyl resonance (a), and causes the T7 and T3 resonances to become overlapped at later stages of the titration (c). Peak (b) is an averaged resonance from the ligand methyl groups intermediate in shift between the bound and free forms of the ligand. (Reprinted with permission from Pavlopoulos, S., Rose, M., Wickham, G., Craik, D.J. (1995) *Anticancer Drug Des.* **10**, 623.)

with some signals in the intermediate exchange regime.

3.2.2.3 **Intermediate exchange.** In this regime, the rate of exchange between bound and free states is comparable to the differences in NMR parameters associated with the exchange. In general, the spectral peaks often become very broad and analysis is difficult. This is the case, for example, for L(Gly). In the methyl region of the spectra shown in Fig. 17, the T7 CH_3 signal moves upfield and the T3 CH_3 signal moves slightly downfield with increasing ligand concentration, as seen previously for L(NH_2) and L(NO_2). However, in contrast to the case for the other ligands, the characteristic broadening of peaks at intermediate ratios is non-Lorentzian, suggesting kinetics in the

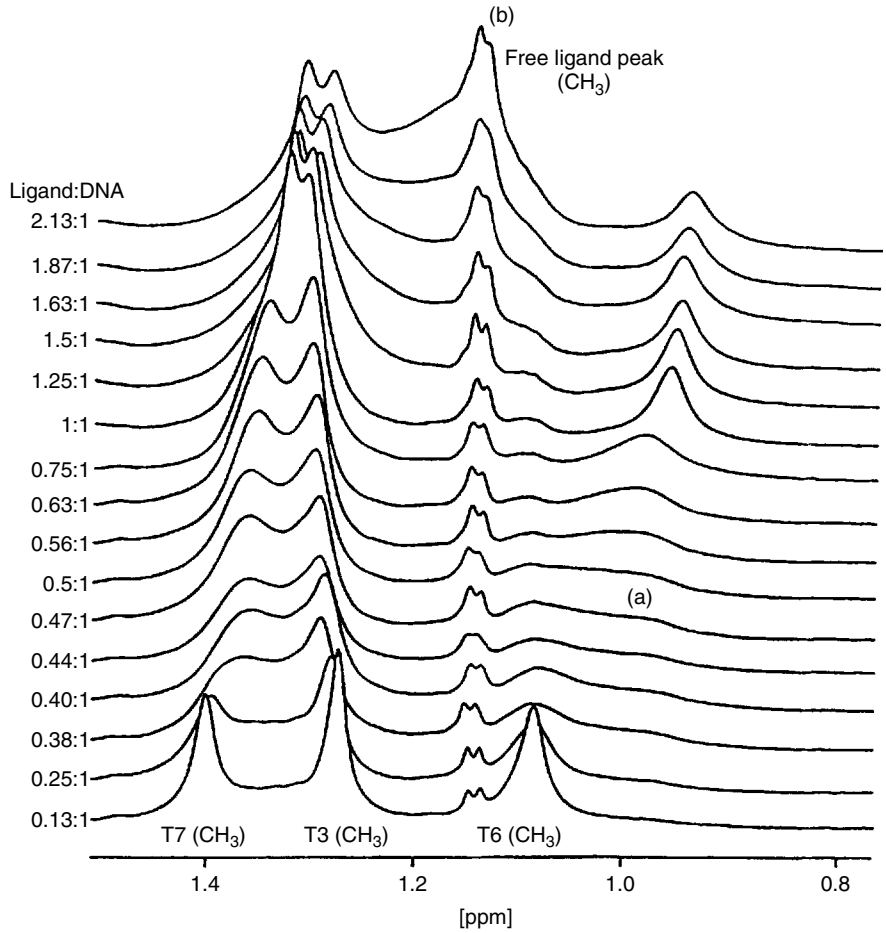

Fig. 17 Expansions from the 600-MHz ^{1}H-NMR spectra for complexes formed between L(Gly) and d(GGTAATTACC)$_2$ showing the methyl resonances. The two small peaks at 1.12 and 1.14 ppm are attributed to an impurity. The complex nature of the T6 methyl resonance at ligand:DNA ratios less than 1 : 1 (a), and the manner in which signal intensity increases at about 1.15 ppm at DNA:ligand ratios greater than 1 : 1 (b), are indicative of intermediate exchange. (Reprinted with permission from Pavlopoulos, S., Rose, M., Wickham, G., Craik, D.J. (1995) *Anticancer Drug Des.*, **10**, 623.)

intermediate exchange regime. The T6 CH_3 peak does not shift in the characteristic fast-exchange manner, but instead, a new broad resonance appears close to the expected position of the bound T6 CH_3 chemical shift on the first addition of ligand, and increases in intensity with increasing ligand concentration. This observation is consistent with the ligand being in slow to intermediate exchange between the free and bound forms, with $k_{off} \approx (\nu_B - \nu_F)$. On the basis of the magnitude of $\nu_B - \nu_F$ for this resonance, k_{off} for L(Gly) is estimated to be 50 s^{-1}, which is significantly slower than that for L(NO_2) and L(NH_2).

At a ligand:DNA ratio of approximately 1 : 1, the ratio of the integrals of the T6 methyl peak and the overlapped T3 and T7 methyl peaks is about 1 : 6. The expected value is 1 : 2, which indicates that the bound ligand methyl peak ($4 \times CH_3$) is overlapped with the T7 and T3 methyl peaks, as observed with L(NH_2) and L(NO_2). When the ligand:DNA ratio is increased beyond a 1 : 1 ratio, a new peak appears at about 1.15 ppm and increases in intensity as the ligand concentration is increased. This new peak corresponds to the methyl peak of the free ligand and its appearance in this manner is consistent with slow exchange on the chemical-shift timescale. To confirm this, spectra of a 2 : 1 mixture of L(Gly) and d(GGTAATTACC)$_2$ were acquired at different temperatures, as illustrated in Fig. 18.

At low temperatures, signals at 1.15 and 1.30 ppm (overlapped with the T7 CH_3 and T3 CH_3 peaks) attributable to the methyl groups from the free ligand and bound ligand, respectively, are distinguishable. As the temperature is increased, a broad peak appears between these two signals (at ~1.22 ppm). At the lower temperatures $k_{off} \leq (\nu_B - \nu_F)$, so that methyl resonances of the ligand have complex characteristics reflecting slow-intermediate exchange. At higher temperatures, $k_{off} \geq (\nu_B - \nu_F)$, so the signal appears as a fast-exchanged average between the free and bound resonances. From a qualitative analysis of the spectra, k_{off} for L(Gly) was estimated to be 50–60 s^{-1} at 283 K.

The fact that some peaks (e.g. the oligonucleotide T7 and T3 methyl signals)

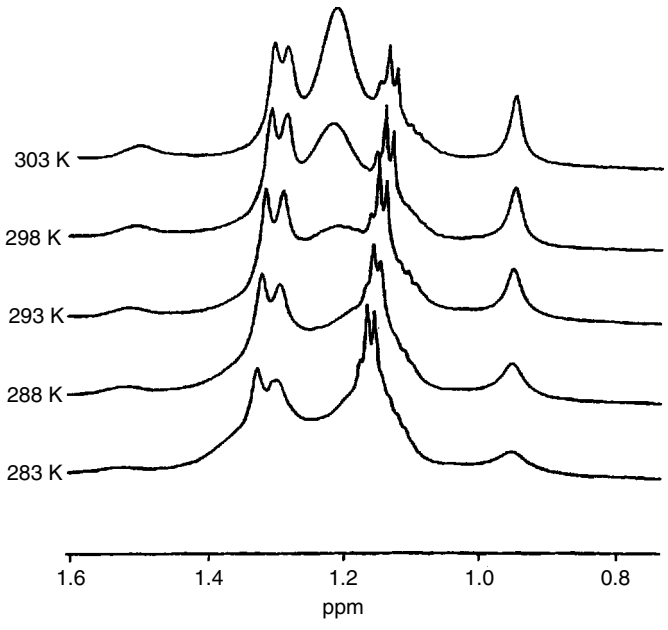

Fig. 18 Expansions of ^{1}H-NMR spectra of a 2 : 1 mixture of L(Gly) and d(GGTAATTACC)$_2$ acquired at different temperatures. (Reprinted with permission from Pavlopoulos, S., Rose, M., Wickham, G., Craik, D.J. (1995) *Anticancer Drug Des.*, **10**, 623.)

exhibit fast exchange, whereas others in the same spectrum of the same complex exhibit slow-intermediate characteristics, is a reflection of the different ($\nu_B - \nu_F$) values for different peaks. This emphasizes the point made earlier that the ''exchange regime'' is a relative expression and depends not only on the rate of exchange but also on the size of the chemical-shift differences involved. In summary, the observations suggest that k_{off} for binding of L(Gly) to the oligonucleotide duplex is much slower than that for the other two derivatives. This provides an illustration of the value of NMR as a quick method for comparing the binding of different ligands and for confirming ligand-binding hypotheses.

The change in binding kinetics may be rationalized by considering the different structure of the L(Gly) ligand relative to the other ligands. It was anticipated that, upon binding to the minor groove, the terephthalamides would adopt a conformation in which the substituent on the central ring would form part of the convex edge of the ligands and therefore be directed toward the ''mouth'' of the groove. Given this binding arrangement, the ligand L(Gly) would have a positively charged alkylamine group positioned to interact with the negatively charged phosphate groups of the DNA backbone. The L(Gly) derivative also has a bulkier substituent than that of the other ligands, and this is also consistent with some differences in its binding.

3.2.3 NMR Techniques

NMR is a particularly versatile tool for the analysis of protein–ligand interactions. As well as being able to observe different nuclei, measurements may be made of a range of different NMR parameters, including chemical shifts, linewidths, coupling constants, and relaxation parameters. In addition, there are several specific NMR techniques that have been applied for the measurement of these parameters. The techniques that are particularly valuable for the study of macromolecule–ligand interactions are described in the following sections.

3.2.3.1 **Chemical-shift mapping.** Chemical shifts are exquisitely sensitive markers of the local charge state and environment. Although it is not possible to construct an accurate model of a binding site from knowledge of the chemical shifts of a bound ligand, a qualitative interpretation of *changes* in chemical shifts of the macromolecule on binding provides significant insight into the location of the binding site. Traditionally, such studies were done using 1D NMR, but are now increasingly done by 2D HSQC spectra. By simultaneously obtaining information on chemical shifts for a large number of sites in a macromolecule and seeing which ones change when a ligand binds, and which ones do not, it is possible to deduce the location of the binding site. This procedure is referred to as *chemical-shift mapping*. A prerequisite of the approach is that the chemical shifts have to be assigned. Chemical-shift mapping by use of HSQC spectra is widely used in NMR screening approaches and we will defer a more detailed discussion on it until Sect. 4.

The relative simplicity of how chemical-shift information localizes binding sites may be illustrated by continuing with the example introduced above of terephthalamide binding to DNA. Figure 19 shows that, upon binding of the terephthalamides $L(NH_2)$ and $L(NO_2)$ to $d(GGTAATTACC)_2$, the DNA protons on the four base pairs between A5 and A8 are perturbed to a much larger degree than protons in the rest of

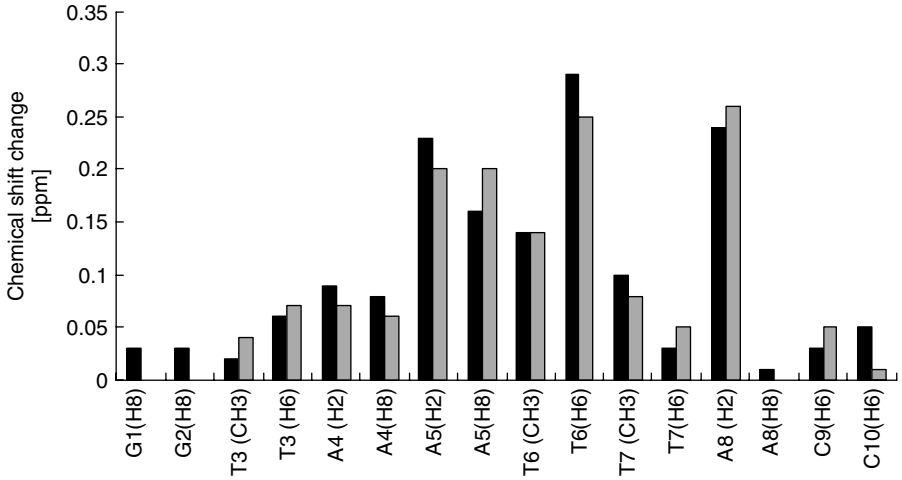

Fig. 19 Chemical-shift perturbations of DNA protons upon ligand binding. The lighter and darker columns represent shifts attributed to L(NO_2) and L(NH_2) derivatives, respectively.

the sequence. It is thus likely that these four residues form the binding site.

A more detailed analysis allows the binding site to be further localized to the minor, rather than to the major, groove in the region of these bases. A4, A5, and A8 are the only residues containing easily detectable minor groove protons (H2). These resonances, which originate from the floor of the minor groove, are shifted downfield with ligand binding, whereas most other resonances are shifted upfield. This observation is consistent with the ligands binding in the minor groove and has been reported for other minor groove binders such as Hoechst 33258 and SN-6999, where adenine H2 protons on the floor of the groove experience deshielding ring-current effects. However, significant chemical-shift changes were also observed for some major groove protons. This illustrates the general point that sometimes, allosteric effects can cause changes at sites not directly involved in binding. In the case of DNA, binding perturbations in the major groove have also been observed for other established minor groove binders such as distamycin, netropsin, and Hoechst 33258. On the basis of NOE and crystallographic data, it was concluded that the effects were caused by distortions of the B-DNA duplex, including changes in the "base roll" of residues within the binding site, upon complexation. Electronic effects arising from the close proximity of charged groups on the ligand to neighboring nucleotides were also found to perturb major groove resonances.

In the case of the terephthalamides, a comparison of the minor and major groove perturbations for a particular residue shows that the minor groove protons are affected to a much greater extent. This is particularly evident for A8, where the H2 proton shifts by approximately 0.25 ppm and the H8 proton is not affected (Fig. 19). It is difficult to conceive of a binding mode in the major groove that would account for such a large effect on the minor groove A8 H2 resonance without a simultaneous effect on the major groove protons of T7

and A8. The observed 1 : 1 stoichiometry of the complex excludes the possibility that the ligand binds to the major and minor groove at the same time. It is more likely, therefore, that binding in the minor groove causes distortion of the DNA structure so that perturbations are observed for the major groove protons of A5 and T6, but not neighboring nucleotides.

Other examples of the use of chemical-shift mapping to locate binding sites have been made for ligands binding to a range of drug targets, including immunophilins, matrix metalloproteases, and DHFR. Some of these examples are described in more detail in Sect. 3.2.4

3.2.3.2 **NMR titrations.** There are a number of advantages in undertaking a titration of ligand against macromolecule or vice versa rather than just examining the final complex. These include introducing the possibility of distinguishing signals from the individual components on the basis of intensities at intermediate stages of the titration in the slow-exchange case and obtaining kinetic and thermodynamic parameters associated with the interaction in the fast-exchange case. Such titrations may be done using either 1D or 2D spectra and are very useful for establishing the exchange regime of the complex, as described in Sect. 3.2.2. A variety of parameters may be monitored in the titration, although the two most common are chemical shifts and linewidths. Examples of such titrations are given in Figs. 16 and 17.

3.2.3.3 **Isotope editing and filtering.** Isotope editing provides a powerful way of distinguishing between the components in a complex without the need for a titration. It is one of the most useful tools for the study of macromolecule–ligand complexes, and indeed the background NMR technology that underpins isotope editing was developed specifically for the study of complexes. The principle of the approach is illustrated in Fig. 20 and is based on the use of isotopes to select for signals from either the ligand or macromolecule, or signals exclusively linking both of them.

The conceptually simplest approach is to uniformly deuterate the macromolecule, thereby removing its signals from ^{1}H-detected NMR spectra, and allowing signals from only the ligand to be observed. This substantially simplifies the spectrum and allows, for example, the bound conformation of a ligand to be determined from NOESY data recorded in D_2O. By rerunning the spectrum in H_2O, additional NOEs to exchangeable amide protons on the protein may be detected, thereby providing information on contacts between ligand and protein. Alternatively, ^{15}N or ^{13}C signals may be introduced selectively into either the ligand or protein, and editing techniques used to select only signals attached to these labels and their proximate protons.

Potentially, the most useful approach involves uniform labeling of one of the components with either ^{15}N or ^{13}C and leaving the other component unlabeled. It is then possible to edit the spectrum by selecting for interactions (either through bond or through space) that connect protons that are both one-bond coupled to ^{15}N or ^{13}C. Alternatively, the spectrum may be filtered to specifically remove such signals, thereby selecting only signals involving protons coupled to ^{14}N or ^{12}C (i.e. on the unlabeled component). It is generally easier to uniformly label the protein rather than the ligand, and editing methods are highly efficient, thus making it easy to visualize just the protein. However, because ligand signals

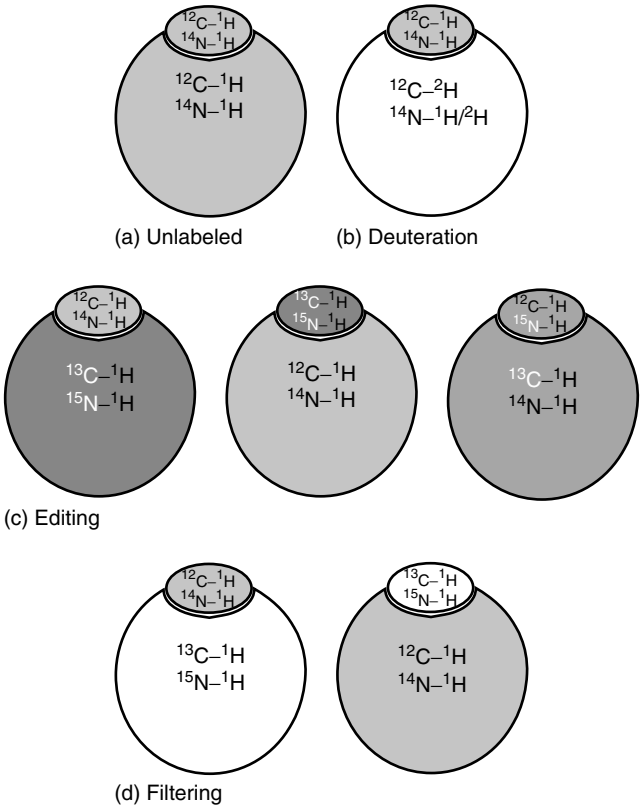

Fig. 20 Isotope editing and filtering can be used to select signals from either the ligand or the protein. (a) Normal protein and ligand with no filtering or editing. (b) Selection of the ligand signals by ^{2}H labeling of the protein. (c) Selection of protein or ligand signals by ^{13}C and/or ^{15}N labeling/editing. (d) Removal of protein or ligand signals by ^{13}C or ^{15}N filtering.

are often of interest, filtering experiments play a valuable role in visualizing them. Unfortunately, filtering experiments are more susceptible to artifacts than are editing experiments.

Another possibility is to use half-edited/half-filtered 2D experiments to detect NOEs that specifically involve interactions between protons attached to ^{15}N or ^{13}C and those that are not. This approach is used, for example, to detect intermolecular NOEs between a labeled protein and an unlabeled ligand. Examples of isotope editing/filtering are given in Sect. 3.2.4.

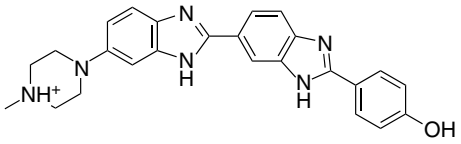
3.2.3.4 **NOE docking.** In many cases, the study of a complex may follow a previous structure determination of the isolated macromolecule and in that case it may be possible to determine much information about a complex by obtaining a relatively small number of NOEs linking the ligand and macromolecule. Gradwell and Feeney recently analyzed factors important

in such NOE docking experiments. In their analysis, a high-resolution X-ray structure of a protein–ligand complex was used to simulate loose distance restraints of varying degrees of quality that might typically be estimated from experimental NOE intensities. These simulated data were used to examine the effect of the number, distribution, and representation of the experimental constraints on the precision and accuracy of the calculated structures. A standard simulated annealing protocol was used, as well as a more novel method based on rigid-body dynamics. The results showed some parallels with those from similar studies on complete protein NMR structure determinations, but it was found that more constraints per torsion angle are required to define docked structures of similar quality. This is because the conformation and orientation of the ligand are defined only by NOEs and not by covalent attachment, as is the case for amino acid side chains in a protein structure. The effectiveness of different NOE-constraint averaging methods was explored and the benefits of using "R^{-6} averaging" rather than "center averaging" with small sets of NOE constraints were demonstrated. With these considerations in mind, it appears that NOE docking can be a very cost-efficient procedure for defining the environment, orientation, and conformation of ligands.

3.2.4 Selected Examples

Applications of the various NMR techniques described are now illustrated with selected examples. The examples have been chosen to give a broad perspective on the types of NMR experiments that can be done and the types of information they provide. Specifically, the first example covers the case of drug-nucleic acid binding and focuses on more traditional NMR experiments, involving relatively standard homonuclear methods. The second example covers binding of moderately large ligands to immunophilins and highlights modern isotope editing techniques. The third example, covering ligand binding to a matrix metalloproteinase (MMP), also highlights the importance of these techniques and shows how relatively simple spectra involving ^{19}F-containing ligands can be very informative. The fourth example describes ligand binding to DHFR, one of the most extensively studied systems by NMR, and illustrates the derivation of a broad range of kinetic and geometric information on intermolecular complexes. The final example, on HIV protease, describes how NMR complements X-ray studies and provides information on dynamic motions within complexes.

3.2.4.1 **DNA-binding drugs.** The NMR approaches that have been used to examine the interactions of minor groove binding drugs with DNA can be illustrated with studies on the bisbenzimidazole-based compound, Hoechst 33258, (**9**). It has been used widely as a fluorescent cytological DNA stain and is also active as an anthelmintic agent. It has activity against intraperitoneally implanted L1210 and P388 leukemias in mice.



(**9**)

Footprinting studies have shown that sequences of four AT base pairs are a prerequisite for strong binding to DNA, consistent with similar observations for other structurally related molecules such

as distamycin and netropsin. The first structural studies of Hoechst 33258 complexed to short sequences of synthetic oligonucleotides were done using X-ray crystallographic methods, but NMR and further X-ray studies followed. Three of the X-ray studies used the *Eco*RI sequence $d(CGCGAATTCGCG)_2$, and another used the sequence $d(CGCGATATCGCG)_2$. Both sequences fulfil the requirement of at least four consecutive AT base pairs, and the resulting complexes showed similar modes of binding. In all of the X-ray studies, the Hoechst ligand was found to bind to the minor groove.

The NMR studies of complexes between Hoechst 33258 and oligonucleotide sequences provided complementary information to the crystal structure data. Because the binding is reversible, the NMR data offer the opportunity to derive information about the kinetics of the interaction. As with the crystallographic studies, the oligonucleotide sequences were designed to contain runs of AT base pairs. Some NMR studies were performed with dodecanucleotide sequences used in crystallographic studies, including $d(CGCGAATTCGCG)_2$, which allowed a direct comparison with the crystallographic data. Experiments were also performed with sequences specifically designed to investigate different aspects of the interaction. The sequence $d(CTTTTGCAAAAG)_2$ was designed to offer two binding sites, and it was shown that two Hoechst molecules interacted with the DNA duplex in symmetry-related orientations at the 5′-TTTT-3′ and 5′-AAAA-3′ sites.

Stoichiometry and kinetics The starting point in studies of ligand–DNA complexes is usually a titration experiment to establish the nature and stoichiometry of the complex. Complexes between the ligand and DNA duplex are obtained by adding small aliquots of ligand solution to a sample of the DNA duplex with one-dimensional ^1H NMR spectra acquired after each addition. The effects observed on the NMR spectrum after each addition reveal whether an interaction is taking place and allow the interaction to be characterized as fast or slow exchange on the NMR timescale. The stoichiometry of the interaction can also be determined from the titration.

In general, the addition of Hoechst 33258 to the oligonucleotide duplexes causes a decrease in the intensity of free DNA resonances and a concomitant increase in the intensity of new resonances, which appear in previously unoccupied spectral regions. This is consistent with the free and bound forms of the DNA duplex being in slow exchange with each other. For example, when Hoechst 33258 is added to $d(GGTAATTACC)_2$, the free DNA signals completely disappear at a DNA:drug ratio of 1 : 1, and the number of new resonances is seen to be twice the number of previously observed free DNA resonances (Fig. 21). This is a common feature of complexes with 1 : 1 stoichiometry and reflects a loss of the dyad symmetry of the duplex attributed to ligand binding.

Upon addition of Hoechst 33258 to $d(CTTTTCGAAAAG)_2$, the free DNA signals completely disappeared at a ratio of 2 : 1 drug:DNA and there was no doubling of the number of DNA resonances in the spectrum. From this, it could be concluded that two molecules were bound per duplex in a manner that retained the dyad symmetry of the DNA duplex. The binding was also determined to be cooperative, in that no intermediate 1 : 1 complex was detected. The formation of a 1 : 1 complex

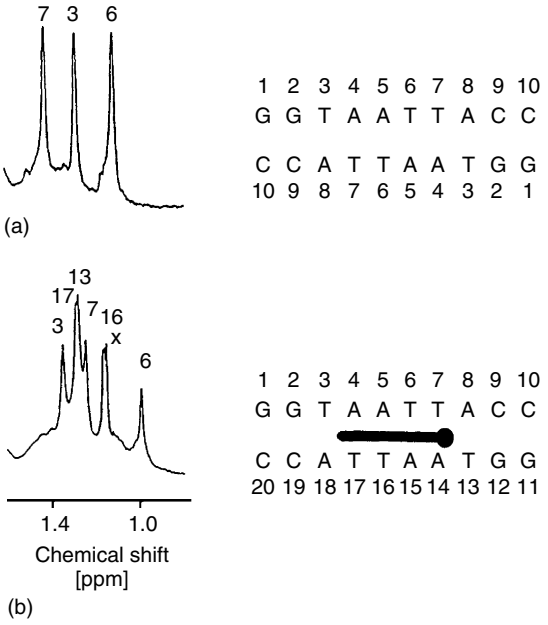


Fig. 21 1D ^{1}H-NMR spectra (recorded at 20 °C) illustrating the thymine methyl region for the symmetrical ligand-free duplex (a) and for the 1 : 1 Hoechst:d(GGTAATTACC)$_2$ complex (b), which is no longer symmetrical because of the ligand binding. x corresponds to a small impurity peak. The DNA strands are numbered to the right of the spectra and the approximate location of the ligand is indicated by a black bar. (Reprinted with permission from Blackwell Publishing Science from Embrey, K.J., Searle, M.S., Craik, D.J. (1993) *Eur. J. Biochem.* **211**, 437.)

would have resulted in a very complicated spectrum at intermediate ligand:DNA ratios, given that resonances arising from the free DNA, the 1 : 1 complex, and the 2 : 1 complex, would have produced four times as many observable peaks relative to the free DNA species. At intermediate ligand concentration, however, only two sets of peaks arising from DNA molecules were detected. In the 2 : 1 complex, only four thymine methyl resonances were detected (1.0–1.5 ppm), as expected for a symmetrical DNA duplex. These are all overlapped in the free DNA spectrum. In the 1 : 1 mixture, only signals from free DNA and from the 2 : 1 complex were detected.

The reversible nature of the Hoechst:DNA interaction is illustrated by the observation of chemical-exchange cross peaks in NOESY spectra of mixtures of free and complexed oligonucleotides. This may be seen in the NOESY spectrum of a mixture of free and complexed d(CTTTTCGAAAAG)$_2$, shown in Fig. 22, in which many chemical-exchange cross peaks are observed between resonances arising from the free and bound oligonucleotide. In a NOESY spectrum acquired at lower temperature, the intensity of these chemical-exchange cross peaks is significantly reduced, indicating that the exchange is slowed at lower temperatures. The exchange rate was estimated to be $<10\ s^{-1}$ at 10 °C.

The ability to observe such dynamic exchange phenomena is one of the strengths of NMR relative to X-ray crystallography, and several examples of these phenomena are described later in the chapter.

Binding site A combination of chemical shift and NOE information can be used to locate and characterize binding sites. Chemical-shift differences between resonances arising from free and bound forms of DNA are indicative of the nature of the interaction. In all studies of

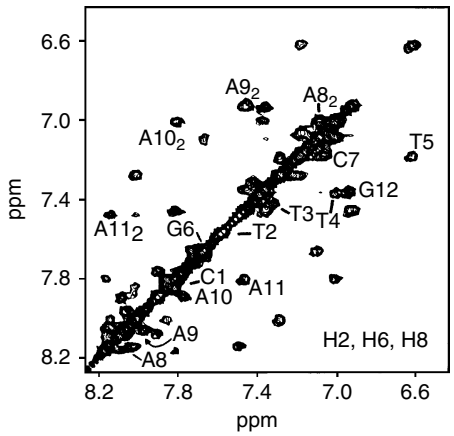

Fig. 22 Aromatic region of NOESY spectrum of a 1 : 1 mixture of Hoechst versus d(CTTTTCGAAAAG)$_2$ recorded with a 200-ms mixing time. Chemical-exchange cross peaks between protons of the free DNA and the 2 : 1 Hoechst:DNA complex are labeled with their identifying base pair. Below the diagonal the H6 and H8 cross peaks are shown, whereas those of the adenine H2 resonances are highlighted in the upper portion of the figure and labeled with a subscript 2. (Reprinted with permission from Oxford University Press from Searle, M.S., Embrey, K.J. (1990) *Nucleic Acids Res.* **18**, 3753.)

the Hoechst complexes described above, significant changes to the chemical shifts of thymine H1′ protons and adenine H2 protons were observed, in contrast to the generally small perturbations observed for the base H8/H6 and CH_3 resonances located in the major groove. Perturbations of this nature are consistent with binding to the minor groove. In some instances, significant perturbations were observed to major groove protons located well within the binding site, reflecting changes in the conformation of the DNA duplex (e.g. base roll, propeller twisting).

Further evidence of minor groove binding is provided by the fact that resonances arising from protons on the floor of the groove, such as the adenine H2 and imino resonances, are shifted downfield, whereas resonances from protons on the minor groove walls, such as the H1′ protons, are shifted upfield. This is a consequence of the ligand's being inserted edge-on into the minor groove. The deoxyribose protons that form the walls of the minor groove are positioned above the π-plane of the aromatic rings and consequently receive upfield perturbations to their chemical shifts. Protons positioned on the floor of the groove, however, generally lie in the plane of the aromatic rings and experience downfield perturbations to their chemical shifts, as illustrated in Fig. 23.

The magnitude of chemical-shift changes is a strong indicator of the location of the binding site. In the case of the 2 : 1 complex with d(CTTTTCGAAAAG)$_2$, the largest chemical-shift changes occur over the 5′-TTTT-3′ and 5′-AAAA-3′ regions of the duplex. In the case of 1 : 1 complexes, where the DNA duplex contains an AT base-pair segment located at the center of the sequence, greater chemical-shift perturbations are observed for resonances in that region, consistent with the binding site being located there.

Assignment of the bound ligand and DNA resonances enables the identification of intermolecular NOEs, which are required for a precise determination of the binding site. The interaction of Hoechst 33258 with the oligonucleotides produced a large number of intermolecular NOEs (~25–30), placing considerable constraints on the structure of the complex and enabling the orientation of the ligand within the binding site to be determined. The NOE contacts observed for different complexes have a few features in common. The contacts generally involve

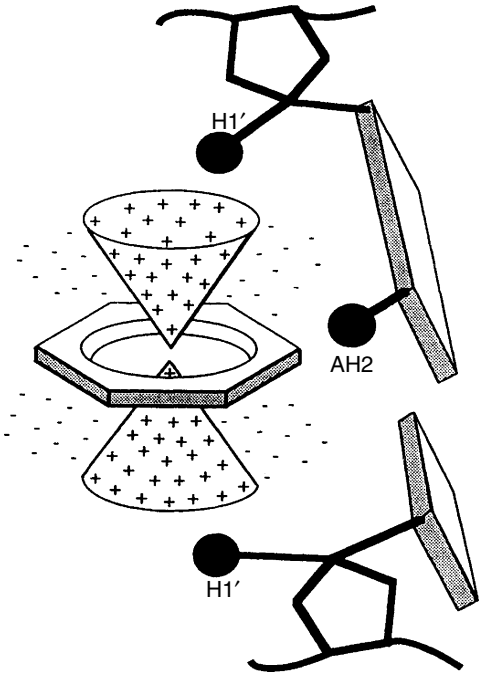

Fig. 23 Schematic representation of ligand-induced ring-current effects on nucleotide protons that form the walls (deoxyribose H1′) and floor (adenine H2) of the minor groove. (+), shielding effects; (−), deshielding effects. (Reprinted with permission from Blackwell Publishing Science from Embrey, K.J., Searle, M.S., Craik, D.J. (1993) *Eur. J. Biochem.* **211**, 437.)

DNA protons associated with the minor groove, such as ribose H1′ and adenine H2, clearly locating Hoechst in the minor groove. Protons of all four spin systems of the ligand show NOEs to protons of the DNA, demonstrating that the interaction occurs along the entire length of the drug. Typically, protons along one edge of the ligand (e.g. NH and H4′/H4′′′′) exhibit close contacts to protons on the floor of the minor groove, showing that the bound drug is crescent shaped and isohelical with the DNA.

Models of the interaction of Hoechst 33258 with the oligonucleotides studied were generated on the basis of the intermolecular NOEs. The models of the 1 : 1 complexes indicated that the ligand interacted with the four AT base pairs located at the center of the sequence. Interestingly, there was no evidence for interactions with GC base pairs on the periphery of the binding sites. In the 2 : 1 complex, the array of contacts observed located the ligand in the minor groove at the center of the 5′-TTTT-3′ and 5′-AAAA-3′ sites, as illustrated in Fig. 24.

As well as defining the *location* of the binding site, intermolecular NOEs can be used to determine the *orientation* of the ligand at that site. In the case of the 2 : 1 complex, the *N*-methylpiperizine moieties were found to point toward the center of the duplex, as indicated by NOEs between the protons from the piperizine ring and the 5′-terminus of the adenine tract (Fig. 24). Corresponding NOEs were also observed between the drug phenolic protons and the 5′-terminus of the thymine tract, as well as the 3′-terminus of the adenine tract of the complementary strand. This model did not indicate any interaction with the central GC base pairs.

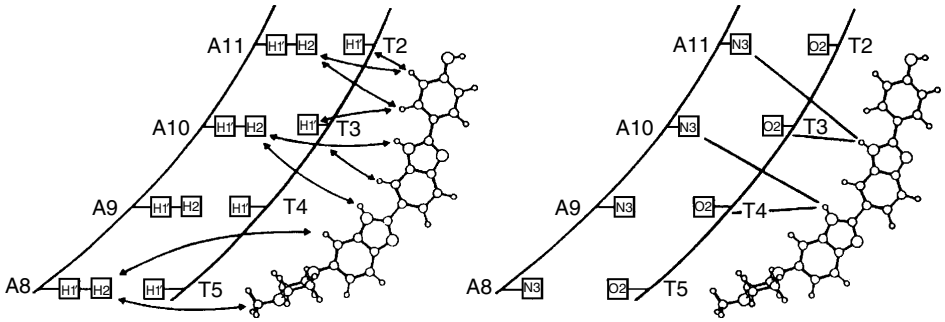

Fig. 24 Schematic representation of Hoechst 33258 bound to the minor groove of the 5′-TTTT sequence. (a) Highlights of some of the NOEs that determine the position and orientation of the Hoechst molecule within the minor groove. (b) Intermolecular hydrogen-bonding scheme. Molecular-modeling studies with an idealized B-DNA helical structure indicate that the benzimidazole H3′ is capable of forming bifurcated interactions with A11N3 and T302, whereas the benzimidazole H3″ hydrogen bonds in a similar manner, but with A10N3 and T402. In the proposed model of the complex, these distances fall within 3.5 Å and are thus within acceptable hydrogen-bonding limits. (Reprinted with permission from Oxford University Press from Searle, M.S., Embrey, K.J. (1990) *Nucleic Acids Res.* **18**, 3753.)

The orientation of the ligand was similarly determined in the 1 : 1 complexes on the basis of the intermolecular NOEs between protons located at the extremities of the Hoechst molecule and protons of the binding site. For example, in the interaction with $d(GTGGAATTCCAC)_2$, NOEs between protons from the piperizine moiety and the H2 and H1′ protons of the dinucleotide fragment d(A5T5)·d(A6T6) were reported.

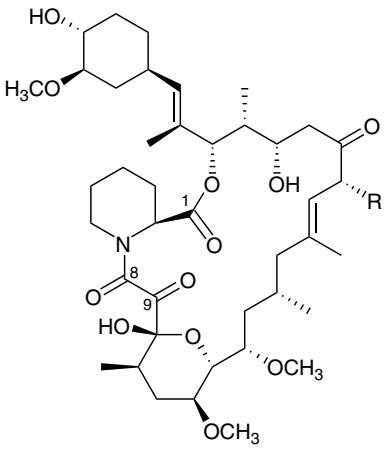
Dynamic processes The binding of the Hoechst molecule to the self-complementary oligonucleotide duplexes in a 1 : 1 ratio lifts the dyad symmetry of the duplexes so that two sets of DNA resonances are observed. This indicates that the drug is in slow exchange between the free and the bound forms. Close examination of the 2D NOE data, however, reveals the presence of chemical-exchange cross peaks between symmetry-related protons on opposite sides of the dyad axis of the DNA duplex. The mechanism by which this occurs has been described as dissociation of the Hoechst molecule from the duplex, followed by a 180°-reorientation and rebinding. The self-complementary nature of the sequences ensures that the same complex is formed for either ligand orientation but with the net effect of interchanging the two strands with respect to the orientation of the Hoechst molecule. The rate at which this process occurs was estimated using cross-peak intensities in the NOESY spectrum. When interacting with $d(GGTAATTACC)_2$ and $d(GTGGAATTCCAC)_2$, the lifetime of the complex in each state ($1/k_{ex}$) was reported to be approximately 0.8 and 0.45 s, respectively. These values indicate a small but significant difference in the affinity of Hoechst for TAATTA and GAATTC sites.

Intramolecular dynamic processes that are fast on the NMR timescale are also observable in the ^{1}H-NMR spectrum of the bound Hoechst molecule. Resonance

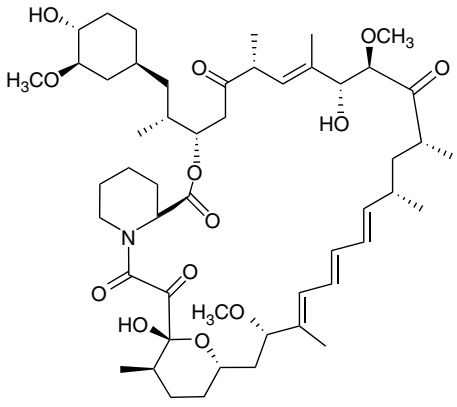
averaging is observed for the H2/H6 and H3/H5 protons of the phenol group, which is consistent with the environments on either side of the ring being averaged by rapid ring-flipping motions about the C4–C2′ axis. This occurs despite the apparent tight fit between the phenyl ring and the walls of the minor groove, which, in a static model of the complex, must present a large barrier for rotation. The rate for this process is as high as 1000 s^{-1}, which is much higher than the rate of interconversion between free and bound forms of the duplex; thus, dissociation of the drug from the complex cannot be the rate-limiting factor for phenol ring flipping. Dynamic fluctuations of the DNA conformation are more likely to provide the rate-limiting step.

Summary of solution studies The data obtained from these NMR studies are consistent with the bound ligand fitting tightly within the minor groove of AT tetramers, with the aromatic rings of the ligand being roughly coplanar. The AT tract provides the key recognition features required for binding, including the narrowness of the minor groove. The importance of van der Waals interactions is evident, given the large number of NOE contacts between the ligand and the walls and floor of the groove. Hydrogen bonding also plays a significant role in stabilizing the interaction, as do electrostatic interactions between the positively charged piperizine ring and the minor groove. Electrostatic interactions are also likely to play a significant role in orienting the ligand within the binding site, as shown in the 2 : 1 complex, in which the piperazine rings point toward the center of the duplex where the positive charge is best stabilized. The information derived from these studies, as well as from NMR studies of the interactions of other minor groove binders with DNA, is useful for the design of ligands with altered specificity or increased binding affinity, with the overall goal being the development of novel drugs.

3.2.4.2 **Immunophilins: Studies of FK506 analog binding to FKBP.** Some of the most detailed investigations of the interaction between ligands and their target proteins have been made for the immunophilin class of proteins. The major FK506 binding protein (FKBP) has a molecular mass of about 11.8 kDa, whereas cyclophilin (Cp) has a mass of about 17 kDa. These proteins are unrelated in amino acid sequence, but both have peptidyl-prolyl cis–trans activities that are inhibited by immunosuppressants that block signal transduction pathways leading to T-lymphocyte activation. FK506 (**10**) and rapamycin (**11**) inhibit the cis–trans isomerase activity of FKBP, whereas cyclosporin A (structure shown in Fig. 3) inhibits that of Cp. NMR has contributed significantly to the understanding of binding interactions to both these proteins.



(**10**) FK506 R = CH_2CHCH_2
(**12**) Ascomycin R = CH_2CH_3



(**11**) Rapamycin

Initial studies on FK506 focused on the structure of the free ligand to aid in the design of further analogs. However, it was established from studies of the cyclosporin A–cyclophilin complex that the conformation of a molecule bound to its target site might be very different from that in the free state. In addition, analog design is assisted by knowing the location of the binding region of the ligand. Studies were therefore undertaken to determine the bound state of the ligand as well as to identify those portions of the drug interacting with the binding protein.

The first investigations involved the analysis of ^{13}C carbonyl chemical shifts of C8 and C9 and the ^{1}H chemical shifts of the piperidine ring of FK506 bound to FKBP. The upfield shifts of the piperidine ring protons, as well as NOEs observed between these protons and aromatic protons of FKBP, suggested that the bound site on FKBP resided in an aromatic-rich domain, and allowed a putative binding site on FKBP to be proposed. It was also evident that the pipecolinyl functionality of FK506 and analogs was involved in the binding face of the ligand.

In another study, a uniformly ^{13}C-labeled ascomycin, (**12**), was prepared, allowing the bound conformation of ascomycin to be determined in the presence of FKBP. The enhanced ^{13}C signals were used to edit the ^{1}H NOESY spectra used for the structural analysis. Not only were the assignments of side-chain methyls made possible by the ^{13}C enrichment but ligand resonances also could be distinguished readily from those of the protein. The conformation of the ligand was determined from NOEs observed in a 3D HMQC-NOESY spectrum. The resulting ascomycin structure (Fig. 25) differed considerably from that of the uncomplexed FK506 obtained by X-ray crystallography, but was similar to that of rapamycin. In particular, the bound ascomycin displayed a trans orientation of the 7,8-amide bond, whereas this bond is cis in free FK506 and trans in rapamycin. The backbone structure of the macrocyclic ring differed from that of uncomplexed FK506, but showed a similarity in the piperidine ring region to that of rapamycin. This study also showed that both the piperidine ring and the pyranoyl moiety of ascomycin are involved in the binding interface in the complex with FKBP. Ligand protons that show NOEs to the protein are in bold in Fig. 25. X-ray studies have since confirmed these results for both the FK506-FKBP and rapamycin–FKBP complexes, showing the trans orientation of the ligand amide bond in the bound conformation, and verifying the involvement of the piperidine and pyranoyl regions of the ligand in the binding interface.

The binding site of the FKBP complex has also been investigated through use of NMR spectroscopy. In early studies, the structure of uncomplexed FKBP was solved using ^{1}H-NMR methods. Although spectral overlap did not allow every

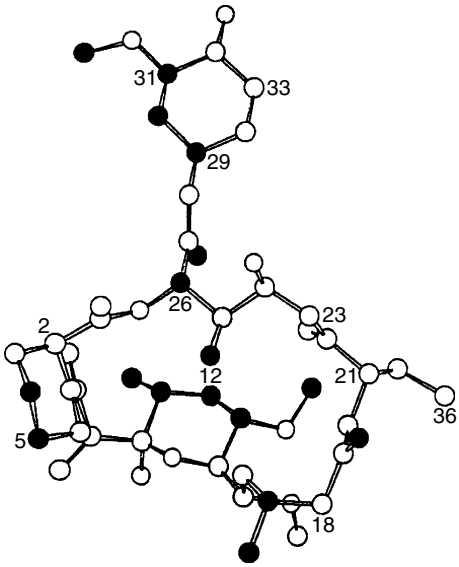


Fig. 25 Three-dimensional structure of ascomycin bound to FKBP. Protons on the ligand that showed NOEs to the protein are denoted by a black shading of the carbons to which they are attached. Although no NOEs were observed from the protons at position 3 to the protein, the upfield shift of their resonances, −1.09 and 0.25 ppm, suggests that they are in close proximity to an aromatic region of FKBP. (Reprinted with permission from American Chemical Society from Petros, A.M., Gampe Jr., R.T., Gemmecker, G., Neri, P., Holzman, T.F., Edalji, R., Hochlowski, J., Jackson, M., McAlpine, J., Luly, J.R. et al. (1991) *J. Med. Chem.*, **34**, 2925.)

structural constraint present to be identified unambiguously, convergent structures defining the global fold of the 107-residue FKBP protein were obtained. Previous biochemical data allowed the extensive aromatic cluster within the core of the structure to be identified as the ligand-binding pocket. The loop regions of the protein between residues 37–43 and 83–90, situated at the open end of the binding pocket, were also of interest. The loops were the least well-defined regions of FKBP and were thought to be flexible, and perhaps involved in the binding interaction. Examination of ^{1}H and ^{15}N chemical-shift changes on addition of ligand supported this notion and suggested that significant structural changes in these loop regions occurred upon ligand binding.

In a later study, a high-resolution structure of the complete ascomycin-FKBP complex was calculated by heteronuclear 3D and 4D NMR. The extra detail afforded by the multidimensional NMR approach allowed the ligand–protein contact area to be located unambiguously and even specific intermolecular hydrogen bonds could be identified. The structure of the complexed FKBP was essentially similar to that of the uncomplexed structure, except that the ''ill-defined'' loop regions between residues 36–45 and 78–92 were found to adopt well-defined conformations in the complexed proteins, as preempted by previous studies. Although this difference may partially be a result of the differences in resolution achieved in the complexed and uncomplexed FKBP NMR studies, generally it was thought that binding involved some rearrangement of the 36–45 and 78–92 loops. This provides a good example of the dynamic nature of protein binding as revealed by NMR spectroscopy.

The dynamic aspects of the ligand–FKBP complex formation have been pursued through analysis of ^{15}N-NMR relaxation data. In particular, the increased backbone mobility for several residues within the 36–45 and 78–95 loops compared with that of the rest of the protein has been noted. From analysis of the ^{15}N

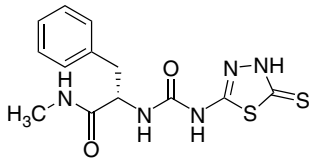
relaxation rates of FKBP complexed with FK506, it was found that flexibility was restricted along the entire polypeptide chain. This confirmed the proposition that the binding interaction of FKBP with ligand involves stabilization and structuring of the protein loops adjacent to the binding site.

In summary, it was possible not only to define the free and bound conformations of the ligand but also to identify the two binding interfaces involved in the interaction and demonstrate a reduction in protein mobility in a defined region of the protein upon binding. This level of analysis was possible because of the tight binding of the FKBP–ligand complex, its small size, and the availability of labeled species. The information proved to be complementary to X-ray crystallographic studies and will help clarify the role of FKBP complex formation in immunoregulation.

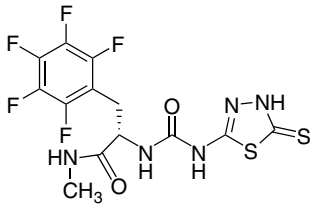
3.2.4.3 **Matrix metalloproteinases.** Matrix metalloproteinases or MMPs, including stromelysin, collagenase, and gelatinase, are involved in tissue remodeling associated with embryonic development, growth, and wound healing. Unregulated or overexpressed MMPs have been implicated in several pathological conditions, including arthritis and cancer, and inhibitors of stromelysin and other MMPs have attracted much interest because of their potential for the treatment of these diseases.

Several NMR structural studies of stromelysin and collagenase complexes have been reported. The secondary structure and global fold have been found to be quite similar for the catalytic domains of both enzymes and their various complexes with ligands. The active site in each enzyme is a cleft spanning the width of the enzyme, with a catalytic zinc atom coordinated by three histidine residues located in the center. Different dynamic properties of active-site residues in stromelysin/ligand complexes and of collagenase with and without bound inhibitor have been reported. It has been proposed that structural and dynamic differences can be exploited in structure-based drug design to achieve broad inhibitor activity against several MMPs or to obtain more selective inhibition.

Of recent interest have been structural data on a novel class of MMP-binding inhibitors, represented by PNU-107859 (**13**) and PNU-142372 (**14**), which contain a thiadiazole moiety that coordinates the catalytic zinc atom through its exocyclic sulfur atom.



(**13**)



(**14**)

Isotope editing/filtering studies played an important role in defining interactions between the ligands and stromelysin. For example, for the stromelysin/PNU-107859 complex, a 3D ^{12}C-filtered, ^{13}C-edited NOESY spectrum recorded on the [^{12}C,^{14}N]PNU-107859/[^{13}C,^{15}N]-stromelysin complex was used to assign protein/ligand NOEs. Of the 11 observed

NOEs between the ligand and protein aliphatic protons, nine involved the aromatic ring of (**13**) and one involved the terminal methyl group. NOEs were observed between (**13**) and protons of Tyr^{155}, His^{166}, Try^{168}, and Ala^{169}. All four of these residues are located in the S_1-S_3 binding sites on one side of the active site. Comparison of 2D $^1H-^{15}N$ HSQC spectra showed that differences between the ^1H and ^{15}N chemical shifts for the stromelysin/**13** and stromelysin/**14** complexes are concentrated in the active site, indicating that no gross conformational differences in protein structure exist. The aromatic rings of (**13**) and (**14**) bind in the same region of the protein.

A region of the 1D ^{19}F spectrum of the stromelysin/**14** complex is shown in Fig. 26. Two separate resonances were observed for the two ortho fluorine atoms of the bound ligand in contrast to the single resonance observed for both ortho protons of stromelysin-bound (**13**), indicating that the ring flip rate (rotation about the $C^{\beta}-C^{\gamma}$ bond) is reduced for stromelysin-bound (**14**) compared to stromelysin-bound (**13**). A ring flip rate of approximately 100 s^{-1} was estimated from the difference in linewidths for the bound ortho and para fluorine atom resonances of (**14**), more than 2 orders of magnitude slower than the ring flip rate for (**13**). The ^{19}F spectrum in Fig. 26 illustrates several general principles that are useful in NMR studies of ligand–macromolecule complexes. First, note that the use of a rare probe nucleus such as ^{19}F produces spectra of elegant simplicity. Because there is no naturally occurring ^{19}F in the

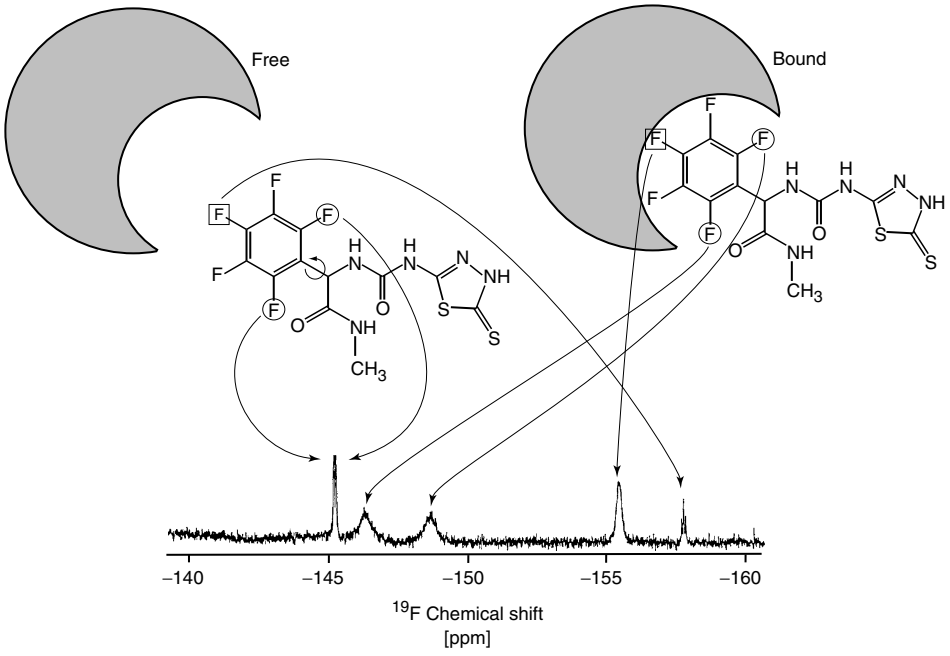


Fig. 26 Region of the 1D ^{19}F spectrum of the stromelysin/PNU-142372 complex. Signals from free (sharp) and bound (broad) PNU-142372 are observed. (Adapted with permission from Elsevier Science from Stockman, B. (1998) *Prog. Nucl. Magn. Reson. Spectrosc.* **33**, 109.)

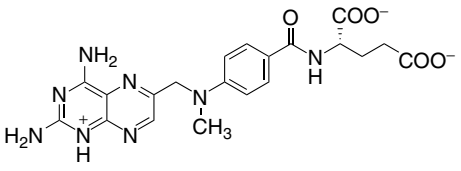
macromolecule, it generates no interfering signals. Second, the offset in chemical shift between bound and free signals reflects the different environment of the bound and free states. Third, signals from the bound ligand are broader than those from the free ligand because of the higher molecular weight of the complex but are still clearly visible for a complex of this size.

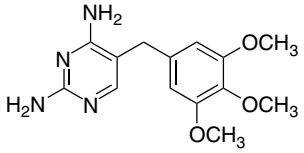
NMR studies have also been reported for ligands bound to collagenase. Interest so far has focused on hydroxamate-containing ligands, where it has been shown that binding causes a decrease in mobility of some but not all active-site residues. Interestingly, some active-site residues adjacent to residues that interact directly with inhibitor were found to have high mobility both in the presence and the absence of inhibitor. This contrasts with what is observed for stromelysin complexed to hydroxamate ligands and a more complete understanding of the dynamics of the respective interactions may provide critical information for drug design.

Hydroxamate-containing ligands have also featured in other NMR studies, this time using TrNOEs to determine their bioactive conformations. TrNOE data were used to determine the conformation of the inhibitors when bound to stromelysin. The NOE-derived structures of the bound inhibitors were used as templates to screen a database of 260 000 compounds. Eighteen of the 23 compounds identified for which stromelysin binding data were available had affinities less than 200 nM, demonstrating the value of deriving a conformationally restricted template for structure-based drug design. This study also demonstrates the close synergy that exists between structure-based design and screening approaches, either *in silico* or experimental.

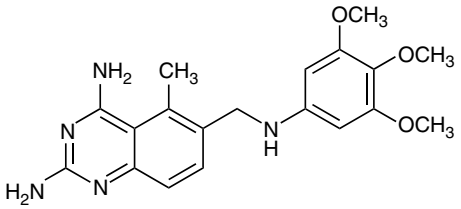
3.2.4.4 **Dihydrofolate reductase.** Dihydrofolate reductase or DHFR is an important intracellular enzyme that is the target of several clinically used drugs, including methotrexate (**15**), an anticancer compound, and trimethoprim (**16**), an antibacterial. These act by inhibiting the enzyme in malignant cells and parasites, respectively. The small size of DHFR (18–20 kDa) makes it amenable to structural studies and there have been numerous complexes determined using both X-ray and NMR methods. The focus here will be on a recent illustrative example of the structure of a new complex of DHFR with trimetrexate (**17**). Trimetrexate was initially investigated as an antimalarial agent but has subsequently been found to have antineoplastic activity against breast, neck, and head cancers. It has also been used as an antibacterial for the treatment of *Pneumocystis carinii* pneumonia in AIDS patients. As seen from the following structures, trimetrexate combines some of the features of trimethoprim and methotrexate:



(**15**)



(**16**)



(**17**)

The three-dimensional structure of the complex of DHFR with trimetrexate was determined using about 2000 distance restraints, 300 angle restraints, and 100 hydrogen-bonding restraints. Simulated annealing calculations produced a family of 22 structures consistent with the constraints. Several intermolecular protein–ligand NOEs were obtained by using a novel approach that monitored temperature effects of NOE signals resulting from dynamic processes in the bound ligand. At a low temperature (5 °C), the trimethoxy ring of bound trimetrexate flips sufficiently slowly to give narrow signals in slow exchange, which give good NOE cross peaks. At higher temperature, these broaden and their NOE cross peaks disappear, thus allowing the signals in the lower temperature spectrum to be identified as NOEs involving ligand protons. Figure 27 shows the structure of the complex, including the orientation of the ligand in the binding site.

The binding site for trimetrexate is well defined and was compared with the binding sites in related complexes formed with methotrexate and trimethoprim. No major conformational differences were detected between the different complexes. The 2,4-diaminopyrimidine-containing moieties in the three drugs bind essentially in the same binding pocket and the remaining parts of their molecules adapt their conformations such that they can make effective van der Waals interactions with essentially the same set of hydrophobic amino acids. The side-chain orientations and local conformations are not greatly changed in the different complexes.

The ring flipping of the trimethoxy aromatic ring mentioned earlier was detected by variable-temperature studies of the spectral line shape. The presence of such dynamic processes involving the ligand appear to be not uncommon in macromolecule–ligand complexes and the ability of NMR methods to detect such phenomena represents one distinct advantage of NMR over X-ray methods of structure determination. Relaxation measurements were also used to probe dynamics of the protein and no large-amplitude motions were found, apart from that at the C terminus. The power of NMR methods for studying dynamics of complexes is further illustrated by an earlier study of the complex of DHFR with methotrexate. In this case, a correlated dynamic rotation of a carboxylate group on the ligand and Arg^{57} of the protein was detected, as illustrated in Fig. 28.

3.2.4.5 **HIV protease.** Because of its essential role in the HIV life cycle, HIV protease is a major target for structure-based design of anti-AIDS drugs. There are now more than 100 structures of HIV protease and protease-inhibitor complexes in the HIV-protease structure database, and the availability of this wealth of high-resolution structural information has been the driving force behind numerous structure-based design programs. Most of the high-resolution structural information on HIV protease has been obtained from X-ray crystallography data. Although there are relatively few examples of HIV protease/inhibitor

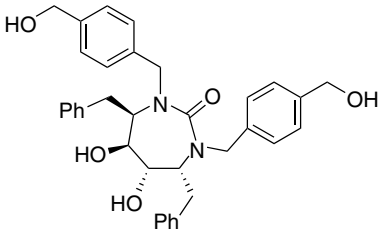
complexes that have been determined by use of NMR spectroscopy, the NMR data, taken together with the structural data from X-ray experiments, have contributed to an understanding of protease-inhibitor recognition and dynamics. Indeed, studies of HIV protease/inhibitor complexes are a powerful example of the way in which complementary information obtained from X-ray crystallography and NMR spectroscopy can be used to facilitate structure-based drug design.

HIV protease/inhibitor complexes have a molecular weight of approximately 22 kDa. Although NMR spectroscopy is well suited for the determination of the structure of molecules in this size range, efforts to determine the solution structure

of the complex were hampered by the fact that the protease undergoes rapid autocatalysis in solution. It required the development of potent inhibitors before NMR studies of the complex became feasible. The first solution structure (Fig. 29) of HIV protease bound to the cyclic urea inhibitor DMP-323 (**18**) was reported in 1996.



(**18**)

The protease exists as a homodimer. Each 99-residue monomer contains 10 β-strands and the dimer is stabilized by a four-stranded antiparallel β-sheet formed by the N- and C-terminal strands of each monomer. The active site of the enzyme is formed at the interface, where each monomer contributes a catalytic triad (Asp^{25}-Thr^{26}-Gly^{27}) that is responsible for cleavage of the protease substrates. The "flap region" is located above the reactive site and is formed by a hairpin from each monomer of two antiparallel β-strands joined by a β-turn. There is little difference between the solution and crystal structures of protease–inhibitor complexes, except in those regions where the polypeptide chain is disordered. However, experiments in solution have allowed access to parameters that are not directly accessible from crystal data. These parameters, such as the amplitude and frequency of backbone dynamics, the protonation states of the catalytic aspartate residues, and the rate of monomer interchange, are essential

(1996), *Protein Sci.* **5**, 495.)

in understanding the interaction of HIV protease with potent inhibitors.

The cyclic urea inhibitor DMP-323 was designed by analysis of crystal structures of HIV protease/inhibitor complexes. A feature common to many of the complexes of HIV protease is a buried water molecule that bridges the inhibitor and Ile^{50} in the flaps. Interactions with this water molecule are thought to induce the fit of the flaps over the inhibitor. In contrast, mammalian aspartic-protease/inhibitor complexes are unable to accommodate an equivalent water molecule. This observation led to the design of a series of cyclic urea-based inhibitors that are capable of displacing the buried water molecule. As well as improving the specificity of inhibitors to the viral protease, displacement of the water molecule was expected to increase the entropic contribution to inhibitor binding and thus enhance the affinity of complex formation. The cyclic urea inhibitors are highly potent and specific inhibitors of HIV protease and for DMP-323, it has been shown in both the crystal structure and in solution that the urea moiety does indeed replace the buried water molecule.

Although DMP-323 replaces one buried water molecule, several others are observed in the crystal structure of the complex. In favorable cases, NMR can be used to estimate the residence times of hydration water molecules, thus providing information about the timescale of the interaction of buried water with the bulk solvent. This analysis led to the identification of a symmetry-related pair of water molecules that may have a structural role in formation of the complex. Such information may prove useful in the design of future cyclic urea inhibitors. An interesting finding was the fact that each of the hydroxyl protons of DMP-323 is in rapid exchange with solvent. This is a surprising result, given that two of these hydroxyl protons are completely buried and form a network of hydrogen bonds with the catalytic Asp^{25}/Asp^{125} side chains. Furthermore, the dissociation rate of DMP-323 is less than $1\ s^{-1}$ under the conditions of the experiment, which is too small to average the chemical shifts of the hydroxyl protons and the bulk water. The observation is ascribed to local fluctuations in the complex that allow solvent molecules to penetrate into the binding site. This conclusion is supported by the observation that the catalytic protons of the Asp^{25}/Asp^{125} side chains in the protease/DMP-323 complex undergo H-D exchange with solvent, even though they are buried and hydrogen bonded to the inhibitor. These studies highlight that even well-ordered structures such as the protease/DMP-323 complex may be flexible on the millisecond to microsecond timescale.

Interestingly, in the DMP-323 complex, both of the catalytic Asp^{25}/Asp^{125} side chains are protonated over the pH range 2–7. The protonated Asp^{25}/Asp^{125} residues form a network of hydrogen bonds with the hydroxyl groups of DMP-323. In contrast, it has been shown that in the complex with the asymmetric inhibitor KNI-272, the side chain of Asp^{25} is protonated, whereas that of Asp^{125} is not. A suggested explanation for this is that both oxygens of the Asp^{125} side chain are deprotonated to accept two hydrogen bonds, one from a bound water molecule and one from the inhibitor. In contrast, the side chain of Asp^{25} is protonated so that it can donate a hydrogen bond to the inhibitor. Consequently, the protonation state of the enzyme is influenced strongly by interaction with specific inhibitors and this

knowledge is essential for a detailed understanding of the protease/drug interactions.

NMR has also been used to study the relationship between flexibility and enzymatic function for HIV protease. For the protease/DMP-323 complex, ^{15}N spin-relaxation studies determined that residues that are flexible correlate well with residues that are disordered in the NMR structure of the complex. For example, residues in poorly defined loops were found to undergo large-amplitude internal motions on the nanosecond–picosecond timescale. In contrast, two regions of the molecule were found to exhibit motions on the millisecond–microsecond timescale. The first of these is at the N terminus of the protein around Thr^4-Leu^5. This is adjacent to the major site of autolysis of the protease and it has been suggested that the rate of cleavage may regulate HIV protease activity *in vivo*. Consequently, the observed flexibility may be important for regulation of protein function. The second region found to be undergoing millisecond–microsecond motion was the tips of the flaps around Ile^{50}-Gly^{51}. In crystal structures, this region of the protease is well ordered and not involved in crystal contacts, although its conformation varies from structure to structure. This motion is interpreted as a dynamic conformational exchange process, which is fast, relative to the chemical-shift timescale. Thus, when the protease is bound to a symmetric inhibitor in solution, this conformational exchange results in the chemical shifts of the flap residues in the two monomers being identical. In contrast, when the protease is bound to an asymmetric inhibitor, such as KNI-272, crystal structures show that each monomer interacts with the inhibitor in a different way. This is reflected in the fact that the chemical shifts of the monomers are different when asymmetric inhibitors are bound. Analysis of spectra from such an asymmetric complex has revealed that the inhibitor is capable of ''flipping'' its orientation with respect to the two monomers without dissociating from the complex. These data again highlight the importance of defining both the structural and dynamic aspects of binding to understand the requirements for potent interactions between HIV protease and its inhibitors.

The development of inhibitors of HIV protease represents a major success for structure-based drug design. When HIV was first identified in the early 1980s, there were no known drugs effective for treatment of infection. A combination of X-ray crystallography, NMR spectroscopy, computer modeling, and chemical synthesis has resulted in the development of several effective HIV protease inhibitors. However, in common with other retroviruses, HIV has a high transcription error rate that results in a rapid mutational rate. One of the results of this is the production of a divergent population of viruses in which the sequence of the HIV protease produced may differ substantially. As a consequence, drug-resistant strains of the virus emerge. Clearly, knowledge of the structural principles that govern inhibition of the protease and the mechanism by which the virus develops resistance will continue to be important in the development of effective new drugs.

4 NMR Screening

In the past, NMR was predominantly used in the design stage of drug discovery rather than the screening stages. Recently, new methods that make use of NMR to screen ligands for binding to a protein

target have been developed and are proving to be a powerful tool in the discovery of new drug leads. This section gives an overview of the various experimental methods, summarized in Table 8, which can be used to screen mixtures of ligands for binding to a drug target. There will also be a brief discussion on the practical considerations that need to be made when designing an NMR screening program.

4.1 Methods

4.1.1 Chemical-shift Perturbation

Chemical shift is a function of the chemical (and hence magnetic) environment that individual nuclei experience. Perturbations of chemical shifts can be used to detect binding of a ligand to a protein target. When a ligand binds to a protein, the local chemical environment is changed, and this is reflected by a change in the chemical shifts of nuclei in close proximity to the ligand-binding site. The most common experiment used in this screening methodology is the $^{1}H/^{15}N$ HSQC that generates a discrete signal for each amide group within the protein. A reference $^{1}H/^{15}N$ HSQC spectrum, which is acquired in the absence of potential ligands, is compared to a spectrum recorded in the presence of ligands and any changes in the amide chemical shifts are indicative of a ligand binding to a location close to the corresponding amide groups. The major advantage of this technique is that, if the NMR assignment of the amide resonances is known, then the site of binding for each ligand can be determined. This is a valuable piece of information in the development of more potent second-generation drug leads. Binding affinities can also be determined by measuring the change in chemical shift as a function of ligand concentration.

One technique that utilizes this screening method for drug design is ''SAR-by-NMR,'' developed by Fesik and coworkers. SAR-by-NMR is a fragment-based drug design approach in which a potent drug candidate is derived by chemically linking two or more small low affinity ligands for a target. In theory, the binding energy of the linked compounds will be the sum of the binding energies of the two individual compounds plus contributions to binding energy attributed to linkage. Therefore, it is possible to generate a drug lead with a nanomolar dissociation constant (K_D) from two milli- to micromolar fragments.

The first step in this process (Fig. 30) involves screening a library of ligands (typically with a MW $<$400) in mixtures of up to 10 for binding to a protein target by comparing the $^{1}H/^{15}N$ HSQC spectrum of an ^{15}N-enriched protein in both the presence and the absence of ligands. Any ligand-induced changes in the chemical shift of the nitrogen and amide proton signals indicate binding of one or more ligands in the mixture to the protein target. The mixture containing the binding ligand(s) is deconvoluted and each individual compound screened to identify the individual ligand(s) responsible for the observed chemical-shift perturbations. Once a binding ligand is identified, analogs can be screened to optimize binding.

A second ligand, which binds at a proximal site, is then identified either from the original screen or by repeating the library screening with the first ligand site bound to the protein. This ligand is then optimized and the structure of the ternary complex determined by use of either NMR or X-ray crystallography. The ternary complex structure provides information on the conformation and orientation of

Tab. 8 A summary of the methods available for NMR screening and their respective characteristics.

Screening methodology	*Signals observed*	*Protein size limit*	*Labelling*	*Binding information obtained*	*K_D limit*	*K_D determined*	*Suitable for HTS (High throughput screening)*	*Mixture deconvolution required?*
Chemical-shift perturbation, e.g. SAR-by-NMR	Protein	<30 kDa	^{15}N protein	Location	10^{-3}–10^{-7} M	Yes	Yes	Yes
STD	Ligand	None	None	Orientation	10^{-3}–10^{-7} M	No	Yes	No
Diffusion-based, e.g. affinity NMR	Ligand	None	^{2}H protein for isotope editing	None	10^{-3}–10^{-7} M	Yes	Yes	No
Relaxation based	Ligand	None	None	None	10^{-3}–10^{-7} M	Yes	Yes	No

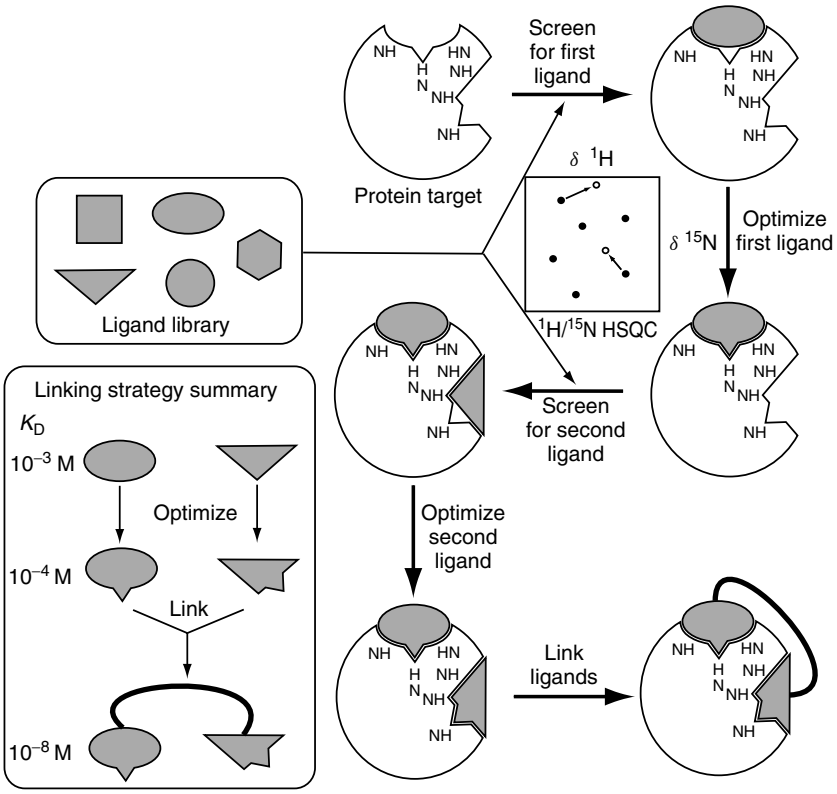

Fig. 30 Summary of the SAR-by-NMR drug discovery methodology. A protein target is screened against a library consisting of small organic molecules by use of the $^{1}H/^{15}N$ HSQC experiment. When two ligands that bind in close proximity are identified, they are linked to form a composite ligand with an increased affinity for the target.

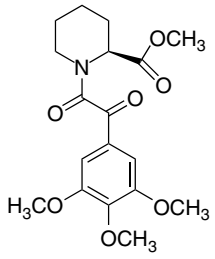
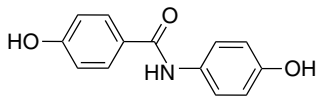
the bound ligands, which facilitates the synthesis of hybrid molecules where the two ligands are joined by a suitable linking moiety.

There are several examples that illustrate the potential of SAR-by-NMR. As noted earlier, FKBP inhibits calcineurin and blocks T-cell activation when complexed to the immunosuppressant FK506. This protein was used as a target for SAR-by-NMR screening and subsequently two ligands, (**19**) and (**20**), were identified with K_D values of 2 μM and 0.1 mM, respectively. A model of the ternary complex between the protein and both

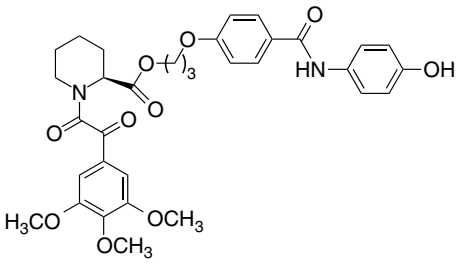


(**19**)

ligands was produced, which indicated that the methyl ester of (**19**) was close to the benzoyl hydroxyl group in (**20**). These two groups were linked with alkyl



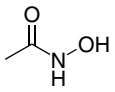
(**20**)



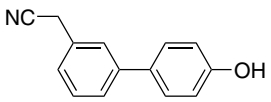
(**21**)

chains of various lengths, with the most active compound (**21**) having a three-carbon linker and a K_D value of 19 nM.

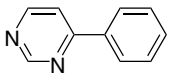
Inhibitors of the MMP stromelysin have also been designed through the use of the SAR-by-NMR screening methodology. As mentioned in Sect. 3.2.4.3, MMPs are involved in matrix degradation and tissue remodeling, with overexpression of these enzymes being associated with arthritis and tumor metastasis. Acetoxyhydroxamate (**22**) was used as one ligand because it was known previously that MMP inhibitors contain a hydroxamate moiety. The K_D value of (**22**) was determined to be 17 mM. To identify a second ligand the protein was screened against a ligand library in the presence of saturating amounts of (**22**). The library was biased for hydrophobic compounds, given that stromelysin demonstrates a substrate preference for a hydrophobic amino acid, and structural studies had identified a hydrophobic binding pocket supporting this observation. From the library screen, a series of biphenyl compounds were identified and analogs of these compounds were synthesized. A biphenyl derivative (**23**) was produced with a K_D value of 0.02 mM. The NMR structure of a ternary complex, consisting of stromelysin (**22**) and the biaryl derivative (**24**) (chosen for its superior aqueous solubility), was determined and indicated that the methyl group of (**22**) was in close proximity to the pyrimidine ring of (**24**). With this information, (**22**) and (**23**) were subsequently linked by different length linkers and the most active compound produced, (**25**), had a K_D value of 15 nM.



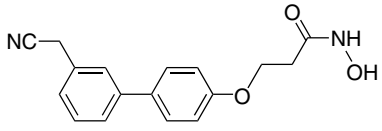
(**22**)



(**23**)



(**24**)

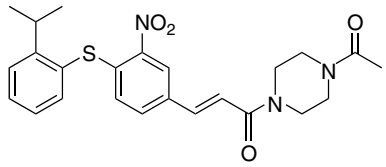


(**25**)

A variation of SAR-by-NMR is to optimize binding or improve the pharmacological properties of known drug leads generated by other methods (e.g. natural products isolation or combinatorial chemistry). A compound can be fragmented into

individual subunits and then alternative fragments can be identified through use of $^{1}H/^{15}N$ HSQC screening. These fragments can then be incorporated into the molecular structure in the hope of improving the binding and/or pharmacological properties of the parent compound (Fig. 31). The alternative fragment must bind in the same location as the corresponding section of the original molecule, making $^{1}H/^{15}N$ HSQC screening method ideal as it provides information on the binding site of ligands.

In a demonstration of this fragmentation method, an antagonist of the interaction between leukocyte function-associated antigen 1 (LFA-1) and intracellular adhesion molecule 1 (ICAM-1) was used as a starting molecule. This interaction plays a role in the inflammatory response and specific T-cell immune responses, and inhibitors have applications in the treatment of inflammation and organ transplant rejection. The *p*-arylthio cinnamide antagonist (**26**) had an IC50 value of 44 nM; however, it was envisaged that the molecule's activity and physical properties could be improved by replacing the isopropyl phenyl group with a more hydrophilic moiety. Screening of a 2500-compound library provided several hits, and analogs of (**26**) were made, which incorporated these ligands in place of the isopropyl phenyl group. Compounds (**27**) and (**28**) had both improved aqueous solubility and pharmacokinetic profiles, with similar or improved activity (IC50 values of 20 and 40 nM, respectively) when compared to that of the parent compound (**26**).



(**26**)

Many compounds bind to human serum albumin (HSA), which significantly reduces their *in vivo* activity and hence their

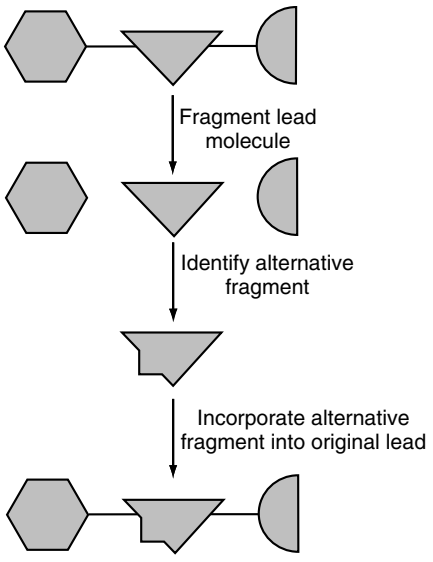


Fig. 31 The fragment optimization approach developed from SAR-by-NMR. A known ligand of a protein is broken into fragments, and small molecules based on the fragments are screened for binding. Any molecules that are found to bind can then be incorporated into the original lead compound with the hope of improving its binding and/or physicochemical properties.

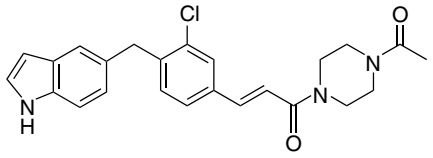
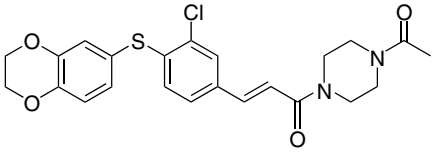
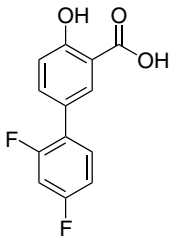


(**27**)

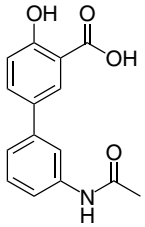


(**28**)

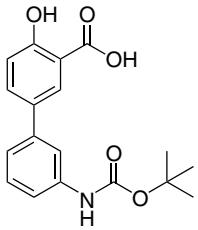
potential as a drug lead. The fragmentation method has recently been used to find analogs of diflusinal (**29**) that have a reduced affinity toward HSA. Diflusinal is a nonsteroidal anti-inflammatory that is more potent, longer acting, and is more tolerated *in vivo* than aspirin. However, 99% of diflusinal is bound to albumin in plasma and, as a result, high doses are required for it to be effective. Structural studies of the diflusinal/HSA-III complex indicated that, by introducing polar functionality to the difluorophenyl moiety, binding affinity to HSA may be reduced without affecting activity. A series of organic compounds analogous to the difluorophenyl fragment were screened using the $^{1}H/^{15}N$ HSQC chemical-shift perturbation method and several alternative fragments were identified. These were incorporated into the diflusinal structure, resulting in a number of analogs (e.g. **30** and **31**) with reduced affinity for HSA but still maintaining some activity. It was predicted that the next generation of compounds would incorporate the fluorine atoms present in (**29**) into leads such as (**30**) and (**31**) because the presence of fluorine increased activity without increasing the affinity for HSA.



(**29**)



(**30**)



(**31**)

Overall, SAR-by-NMR is already showing great promise as a major new tool in drug design, but it has a few limitations. First, the screening of large ligand libraries and any subsequent deconvolution steps can be expensive, in that a large amount of ^{15}N-labeled protein is needed. However, as already noted, recent advances in cryoprobe technology has reduced the amount of protein required. The use of smaller, more druglike libraries such as that described in the SHAPES ideology could also be used to reduce the amount of protein required for screening. The second limitation is that the NMR assignments for

the protein must be known or determined. This limits the size of the protein target to 30 kDa or less, although this value will presumably increase as TROSY-based NMR technologies for structure determination advance. The method also requires the comparison of $^{1}H/^{15}N$ HSQC of the protein in both the absence and the presence of ligands. Changes in solvent conditions such as pH, polarity, salt concentration, and viscosity may cause shifts in amide resonances, leading to false positives.

Recently, a protocol was described that screens ligands using the $^{1}H/^{15}N$ HSQC experiment but includes a mass spectrometry–prescreening step. Ligand mixtures are added to a protein target and then subjected to size-exclusion chromatography, which separates ligand/protein complexes from free ligands. The identity of the bound ligands can then be determined using MS data and, once identified, screened by $^{1}H/^{15}N$ HSQC to determine the location and specificity of binding. This MS/NMR methodology reduces the amount of ^{15}N-labeled protein required because only a fraction of the library is screened by NMR and there is no deconvolution step.

4.1.2 Magnetization Transfer Experiments

Proteins are composed of a large network of dipole–dipole interactions, resulting in the efficient transfer of magnetization throughout the molecule. The saturation transfer difference (STD) experiment (Fig. 32) uses this phenomenon to detect the binding of ligands to a protein. It relies on the fact that saturation of a single protein resonance results in saturation of all protein resonances and any ligands that bind to the protein, provided they are not affected directly by the selective saturation pulse. The STD experiment is able to detect the binding of ligands with a K_D between 10^{-3} and 10^{-8} M.

An STD experiment consists of irradiating an isolated protein resonance (either at low or high field) with a series of pulses that saturate the entire protein and any binding ligands. This results in a spectrum

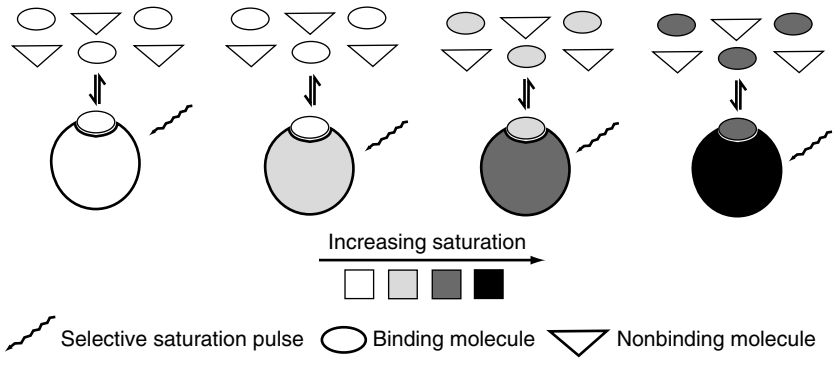


Fig. 32 A schematic representation of the saturation transfer effect. The protein resonances are saturated (indicated by shading) by a selective pulse by spin diffusion. Resonances of nonbinding ligands (triangles) are not affected by this pulse but ligands that are interacting with the protein (ellipses) will also become saturated. These interacting ligands are transferred to solution through chemical exchange where they are detected. (Reprinted with permission from Wiley-VCH from Craik, D.J. (Ed.) (1996) *NMR in Drug Design*, CRC Press, Boca Raton, FL, pp. 1–476.)

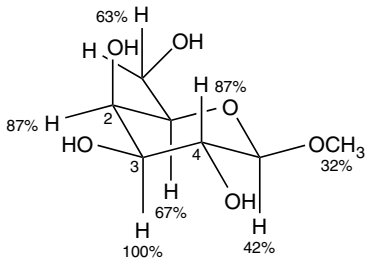
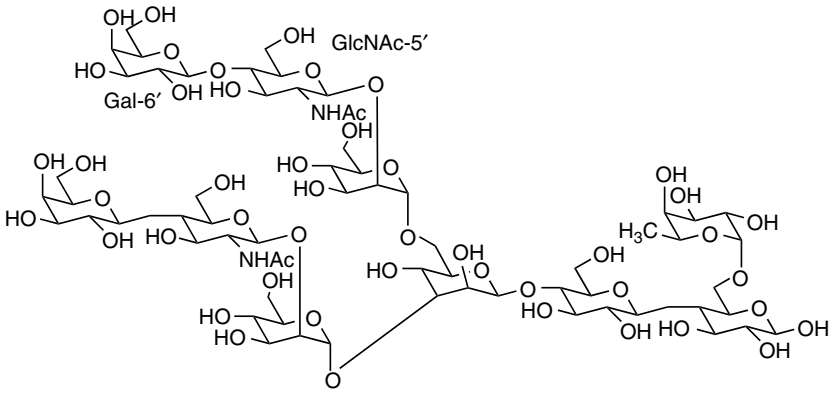
containing reduced signal intensities from both the protein and the ligands that bind to it. A second spectrum of the protein and ligand library is then recorded with the saturation pulses off-resonance. Subtraction of these two spectra results in the STD spectrum that shows only those ligands that bind to the protein (residual protein resonances are removed using a T_2 relaxation filter). This subtraction occurs internally through phase cycling after every scan, to reduce artifacts attributed to temperature or magnetic field variations.

An STD can be added to most forms of NMR experiments including COSY, TOCSY, NOESY, and inversely detected ^{13}C or ^{15}N spectra. A high-resolution magic angle spinning (HR-MAS) STD experiment has been developed to study the binding of ligands to a protein immobilized on a solid support. HR-MAS STD NMR provides a way of obtaining ligand-binding information for proteins that are difficult to work with in solution attributed to either poor solubility or conformational changes. In addition to screening ligands for binding to a protein, the binding epitope of a molecule can also be determined by examining the intensities of ligand resonances. The proton signals that have the strongest signals will correspond to those that are part of the ligand's binding epitope. For example, it was shown that when methyl β-D-galactoside (**32**) bound to *Ricinus communis* agglutin I the H2, H3, and H4 were saturated to the highest degree (values on structure indicate relative signal strengths) and hence were in close proximity to the protein protons. This analysis was subsequently extended to the decasaccharide NA_2 (**33**) and demonstrated that the Gal-6′ and GlcNAc-5′ residues bind edge-on to the protein, with the binding contribution of the terminal galactose residue being the greater.



(**32**)

There are a number of advantages in using the STD experiment for the detection



(**33**)

of ligand binding. The saturation transfer effect is an efficient process, which results in high sensitivity, and hence only small quantities of protein are required (nanomolar concentrations of a protein with MW >10 kDa). In addition, protein size is noncritical; in fact, as the protein becomes larger, the saturation transfer effect becomes more efficient. The acquisition time for each experiment is also quite short and, because the experiment is ligand observed, no deconvolution of mixtures is required, making this a good technique for high-throughput screening of large ligand libraries. Unlike the chemical-shift perturbation techniques, STD experiments provide no information on the site of ligand binding.

A second variation of saturation transfer experiment has been devised, which uses the transfer of magnetization from the water. Water is intimately associated with proteins being bound either within or on the surface of the macromolecular structure. Saturation of the water resonance will lead to protein saturation through a variety of mechanisms, including saturation of the αH resonances, saturation of exchanging protein resonances, and NOE interactions between water and the protein. If a compound is bound to the protein, it will also become saturated, and this effect can be used as an indication of ligand binding.

4.1.3 **Molecular Diffusion**

Molecules can be distinguished on the basis of their diffusion coefficients, which are related to molecular size. Large macromolecules, such as proteins, diffuse more slowly than small molecules and it is this size difference that can be exploited to screen for ligand binding. If a small molecule binds to a protein target, its diffusion coefficient is altered to a value more like that of the protein. Therefore, by utilizing a diffusion filter, resonances generated by small molecules that do not bind to the protein can be removed from the spectrum.

Diffusion editing is achieved with the use of a pair of gradient pulses. If field homogeneity is ignored, then all spins experience an identical magnetic field despite having different positions throughout the sample. The application of a field gradient has the effect of making field strength dependent on position. Under the influence of the gradient pulse, the phase of individual spins become dependent on their position within the sample and hence the spins are spatially "encoded." If diffusion does not occur, this spatial encoding is fully reversible by a second gradient of inverse polarity and no loss of NMR signal will occur. However, the second gradient pulse will be unable to "decode" the spins that have undergone diffusion and the resulting NMR signal will be reduced. Acquiring spectra of a sample with and without the diffusion filter and then subtracting them allows the ligands binding to the protein to be identified. This filtering method can be used for both 1D and 2D experiments and can be "tuned" by altering the strength and duration of the gradients.

Because the ligand signals are being observed in this screening method, no convolution of the ligand mixture is required, given that any signals can be assigned directly to individual compounds within the mixture. However, signals from the protein are always present, which can pose a problem in interpreting spectra. An isotope-edited version of the diffusion experiment has been designed to avoid this problem, although labeled protein is required. Generally, there is no requirement for labeling of the protein

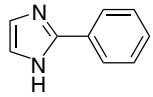
target or for the protein resonances to be assigned and thus, in theory, there is no size limit on the proteins that can be screened by use of this method, although no information is obtained on the location of ligand binding. However, if the protein is large, then the transverse relaxation time may be too short to observe the bound ligands in the diffusion-edited spectrum. Only one sample, containing protein and ligands, is used to obtain both reference and screening data and therefore differences between the sample and reference spectra caused by addition of the ligands (pH, salt concentration, etc.) are avoided.

Diffusion-filtered NMR screening requires that there is a significant difference in observed translational diffusion between the free and bound states. The ligands are in fast exchange on the diffusion timescale and as a consequence the observed diffusion coefficient for binding ligands is an average between the free and bound diffusion values. Free ligands diffuse at a much faster rate than those in the bound state, and thus just a small amount of free ligand has a considerable effect on the observed average diffusion coefficient. This effect may be significant enough to reduce the difference between binding and nonbinding ligands, making it more difficult to interpret results.

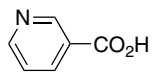
A methodology based on diffusion filtering named "affinity NMR," has also been used to screen for binding. Diffusion-edited NMR experiments were able to identify two known binding tetrapeptide ligands of vancomycin from a mixture of 10 peptides. Similarly, the application of diffusion-editing experiments has been demonstrated by differentiating ligands of stromelysin from a mixture containing nonbinding compounds.

4.1.4 **Relaxation**

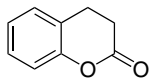
Like diffusion, the transverse relaxation time (T_2) of molecules is also dependent on molecular size. Large molecules, such as proteins, have a short T_2 and hence exhibit broad NMR signals, whereas small molecules have a longer T_2 and hence narrower linewidths. Therefore, if a small molecule ligand binds to a protein, its T_2 value will decrease and a line-broadening effect of bound ligand signals can be observed. Alternatively, a relaxation filter can be used to remove signals from molecules with a short T_2 value. Subtraction from a reference spectrum will result in a spectrum containing only those ligands that bind to the protein. The ability to identify binding ligands using relaxation filters has been demonstrated using FKBP. A mixture of nine compounds consisting of one known ligand of FKBP, 2-phenylimidazole (**34**), and eight nonbinding compounds (e.g. **35**–**37**) were screened and only signals from (**34**) were observed.



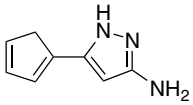
(**34**)



(**35**)



(**36**)



(**37**)

4.1.5 NOE

NOE experiments can also be used to identify ligands that bind to protein targets. Small molecules have a fast tumbling rate and, as a consequence, generally exhibit small positive NOEs. In contrast, large molecules such as proteins generate strong negative NOEs because of their slow tumbling time. When a small molecule binds to a protein, its tumbling rate is slowed to that of the protein and it exhibits strong negative NOEs. On dissociation, these are transiently retained and are known as *transfer NOEs* or *TrNOEs* (Fig. 33). TrNOEs and those arising directly from the free ligand can be distinguished by the rate of signal build up. TrNOEs accumulate significantly faster and therefore can be selected by using shorter mixing times in the NOE experiment.

In practice, a 2D NOESY spectrum of the mixture of potential ligands in the absence of protein is recorded and all molecules exhibit small positive NOEs. The experiment is then repeated in the presence of protein and molecules that bind display negative TrNOEs. Subtraction of the two spectra provides signals arising from only those compounds that bind. These TrNOEs can be interpreted to provide information regarding the bound conformation of the active ligands. However, when analyzing the conformational data, care must be taken to ensure that the ligands are in fast exchange and that the observed TrNOEs are not affected by contributions from spin diffusion. Relative binding affinities between ligands can also be determined by comparison of TrNOE signal strength but, again, the fast-exchange regime and spin-diffusion effects need to be taken into account. If all ligands are in fast exchange, the stronger binding ligands occupy more binding sites and thus give larger TrNOE intensities. Because of the need for an averaging effect, brought about by fast chemical exchange, TrNOE experiments are limited to those ligands with a K_D value from 10^{-3} to 10^{-7} M. The spectral properties of excess ligand in solution are evoked by small fractions of bound molecules, greatly enhancing sensitivity.

TrNOE experiments have been used to identify a bioactive disaccharide from a library of 15 mono- and disaccharides that bound to *Aleuria aurantia* agglutinin. Another study has described the identification of a silalyl Lewis mimetic (**38**) that binds to E-selectin from a library of 10 compounds. As well as being used to detect binding, TrNOEs may also be used to determine bound ligand conformations, as described earlier in this chapter.

A second technique that uses NOEs to detect binding is NOE pumping. This

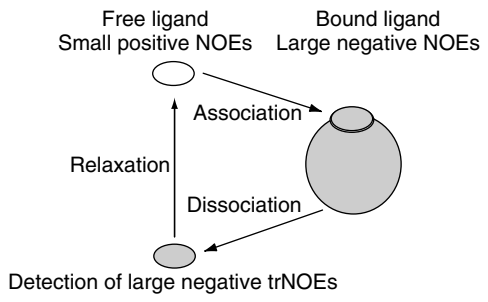


Fig. 33 A schematic representation of the TrNOE experiment used to detect ligand binding (as described by Mayer, M., Meyer, B. (2000) *J. Med. Chem.* **43**, 2093). The free ligand (white ellipse) exhibits only small positive NOEs, although binding to the large protein target results in the generation of large negative TrNOEs. The appearance of these large negative TrNOE signals can be used to identify ligands within a mixture that are binding to the protein and also provide some information on the bound conformation of the ligand.

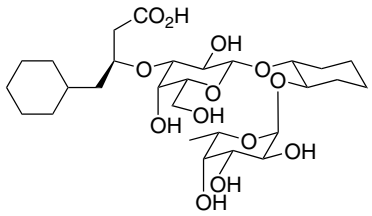


(**38**)

method was designed to alleviate some of the problems associated with the diffusion-edited screening methods. Signals from ligand molecules are removed using a diffusion filter and then transfer of signal from the protein to bound ligands by NOE occurs. The inverse of this is possible (known as *reverse NOE pumping*), which uses a relaxation filter to attenuate the protein resonances, after which the signal is transferred to the protein by NOE. Ligands may lose signal either by relaxation (for a free ligand) or through relaxation and NOE transfer (for a bound ligand). Therefore, by subtracting spectra (which is done internally to reduce subtraction artifacts) from experiments with and without NOE pumping to the protein, the binding ligands can be detected.

4.1.6 **Spin Labels**

Spin–spin relaxation rates are proportional to the product of the squares of the gyromagnetic ratios of the involved spins. The gyromagnetic ratio of an unpaired electron is significantly larger than that of a proton and therefore any spins influenced by this electron will have substantially shortened relaxation times. The resonances of protons that are within 15–20 Å from the unpaired electron will experience this effect and be significantly broadened. The introduction of a short spin-lock period will significantly reduce the intensity or quench these signals.

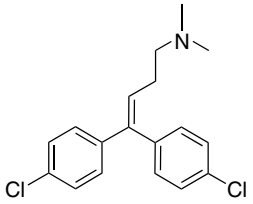
The spin-label method can be used as either a primary screening method or to identify a second ligand-binding site. The primary screening method requires residues around the binding pocket of the target to be spin labeled. Residues suitable for this labeling include lysine, cysteine, histidine, glutamate, aspartate, tyrosine, and methionine. Any ligands that bind to the protein in close proximity to the spin-labeled residues will be able to be identified. To screen for second-site ligand binding, the known first-site binding ligand is spin labeled. A reduced signal will be observed for any ligands that bind simultaneously and in close proximity to the first ligand-binding site. In addition, the degree of reduction in signal intensity gives an indication of the orientation of the second ligand in relation to the first, given that the effect of the spin label is inversely proportional to the distance separating the electron and proton. This information is valuable in the design of linkers to join the two ligands.

There are several advantages to using the spin-label screening method. Currently, it is the only method that can detect ligands that bind to the protein simultaneously, unlike other methods that can produce false positives if the first ligand-binding site is not fully saturated. The concentration of protein required for screening is relatively small ($\sim$10 μM) because of the substantial enhancement of the relaxation rate by the spin label. The protein can also be unlabeled and partially purified and there is no molecular weight limit. The spin labels also quench protein signals, making interpretation of spectra easier. The experiment is easy to set up and analyze, making

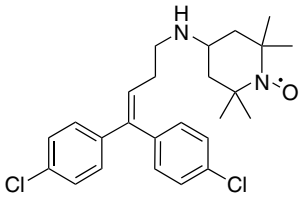
it amenable to automation. It is also insensitive to small changes in solvent conditions, which can generate false positives in other methods. The information obtained on the orientation of ligands is also valuable and makes it an alternative to the chemical-shift perturbation methods when the proteins are large and NMR assignments have not been made.

A disadvantage of the method is the requirement for spin-labeled proteins and ligands. In addition, any ligands with slow dissociation rates will show no averaging of relaxation rates and therefore tightly binding compounds ($K_D < 10^{-6}$ M) will produce false negatives. Protein spin labeling must occur adjacent but not within the binding site to minimize alteration of its binding properties.

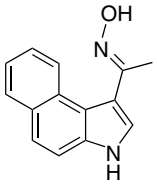
The antiapoptopic protein Bcl-xL is responsible for the reduced susceptibility of cancer cells to undergo apoptosis and is therefore a target for the development of new anticancer agents. The structure of a previously identified ligand for Bcl-xL (**39**) was modified to incorporate a TEMPO spin label (**40**). By use of spin labeled (**40**), an eight-compound library was screened for simultaneous binding to Bcl-xL. From this library, an aromatic ketoxime (**41**) was identified as binding simultaneously with and in the vicinity of (**40**). Analysis of relaxation enhancements revealed that the protons around the indole ring were closest to the spin label.



(**39**)



(**40**)



(**41**)

4.2 Practical Considerations

4.2.1 Screening Approach

The first step in using NMR screening is to select a suitable screening method for the target protein being used. Table 8 lists the characteristics of each NMR screening method. The choice of experiment will be determined by the characteristics of the protein target and the information that is desired from the screen. For example, the SAR-by-NMR method is suitable only for small, easily expressed proteins because the NMR assignments for the target need to be known so the location of binding can be determined, and a large amount of ^{15}N-enriched protein is required. If a simple ''yes/no'' answer on ligand binding is wanted, then the shorter, less resource intensive ligand-observed experiments (e.g. STD, diffusion-edited, or TrNOE) may suffice.

It is also important to determine the correct NMR solvent conditions for the screening procedure. These should facilitate good solubility, with little precipitation or aggregation, and acquisition of good

quality data; maintain protein structure and activity; and provide a sufficient buffering effect to allow for ligands to be added. Two methods that permit the screening of a range of solvent conditions to determine without the need for a large amount of protein are the microdialysis button test and the microdrop-screening method.

4.2.2 Library Design

Effective design and management of the ligand library to be used for screening is essential if successful results are to be obtained.

4.2.2.1 **Ligand properties.** Diversity of ligands is an important factor to consider in the design of a library for NMR screening and there are a number of factors to take into consideration. Although it would seem logical to maximize diversity, this may not always be the most efficient approach. If the system being studied exhibits neighborhood behavior, then maximizing diversity is a good option. Neighborhoods are regions of multidimensional molecular space defined by a set of molecular descriptors. By the choice of a molecule that is in the center of a neighborhood, it is possible, in theory, to represent all molecules within that molecular space. By spreading out the molecules that are selected for the library so that each neighborhood does not overlap, diversity is maximized.

However, if neighborhoods are only small, then compound libraries must be very large so that the neighborhoods overlap and hence all molecular space is covered. In addition, some systems do not exhibit neighborhood behavior and relatively small changes to the structure of a compound may lead to large changes in its binding affinity for the target. Maximizing diversity may also be inefficient because many molecules do not possess physicochemical characteristics that are suitable as the basis for a drug. In practice, the more that is known about the drug target, the less diverse and more focused the library can be. However, if the library is too focused, then some outlying ''new'' ligand type for the target being screened may be missed.

One strategy for library design is to select compounds that have druglike characteristics. A simple set of rules, determined by Lipinski and coworkers, for determining whether a compound is druglike is known as *the rule of 5*. According to this set of criteria, the majority of orally available drugs have five or fewer hydrogen bond donors, 10 or fewer hydrogen bond acceptors, a log P of less than 5, and a molecular weight less than 500. Additional factors that can be taken into consideration include the number of heavy atoms, rotatable bonds, and ring systems. Another study has revealed that there are a number of frameworks and side chains that commonly occur in many drugs. Drug molecules, from the comprehensive medicinal database, were broken down into systems consisting of frameworks (Fig. 34) and side chains. Analysis of these two structural features revealed that approximately 50% of all known drugs could be represented by only 32 different frameworks. When atom type and bond order were included in the analysis, 41 frameworks were found to describe 24% of all drugs. A similar analysis of side-chain frequency indicated that approximately 70% of all side chains present in the compound database analyzed were from the top 20 occurring side chains.

The presence of these common frameworks and side chains has been exploited in the SHAPES methodology for NMR

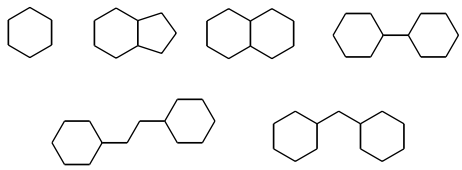


Fig. 34 Examples of molecular frameworks from the SHAPES library.

screening. This strategy employs a small focused library based on these common frameworks and side chains to screen against protein targets through the use of relaxation and NOE experiments. The advantages of this approach are that the library is small and hence only relatively small amounts of protein are required and any hits from the library will possess druglike characteristics. However, a disadvantage of the method is that it is unlikely to yield new drug types, given that the library is based on known drug frameworks.

Diversity of molecular type is not the only factor that must be taken into account when designing a library to be used in an NMR screening program. Because the screening occurs in an aqueous solution, the organic compounds chosen for the library must demonstrate reasonable solubility in the aqueous conditions used. In general, compounds are dissolved in dimethyl sulfoxide (DMSO) and then added to the protein solution at the appropriate concentration. Currently, there are no good methods for determining the solubility of a wide range of compounds before screening commences. A simple method is to dilute the DMSO solution in buffer and observe whether any precipitation or aggregation occurs. However, this method will not be suitable for compounds that precipitate or aggregate over several hours, and solutions that appear clear may still contain high MW aggregates, which will cause false positives in experiments such as the diffusion, relaxation, and TrNOE methods.

It is also preferable to choose ligands that are synthetically accessible and/or possess suitable moieties to build upon or link to other fragments. This is especially important in the SAR-by-NMR screening methodology because this relies on the ability to link individual fragments to form a more potent drug lead. If the ligands to be linked are not synthetically accessible or do not possess suitable linking functional groups, then this process is severely hindered.

4.2.2.2 **Mixture design.** The optimal number of compounds per mixture is dependent on the screening method. For ligand-observed experiments, the limiting factor for the number of compounds in a mixture is spectral overlap. Ligands need to be chosen so that spectral overlap is minimized, making interpretation of the resulting data far simpler. In theory, protein-observed experiments could have a large number of compounds per mixture, which would both minimize screening time and the requirement for large amounts of protein. However, because the experiments are protein observed, deconvolution of the mixtures and rescreening of each individual compound are required to identify any hits. Therefore, the number of compounds per mixture is dependent on the hit rate in the screening procedure, given that the greater the hit rate, the more deconvolution steps that are required and consequently more protein and spectrometer time are needed. The number of experiments required is at a minimum

when the number of compounds is equal to 1/(hit rate)$^{1/2}$; thus, with a hit rate of 10%, the optimal number of compounds per mixture is three. In addition to these factors, if the hit rate is high, then it is likely that several compounds within a mixture containing a large number of compounds may compete for the same binding pocket, which may lead to false negatives.

In mixtures of organic compounds, the possibility of interactions between compounds, such as reactions or ion pairing, is also possible and should be taken into consideration, especially when one uses large numbers of compounds per mixture. It has been demonstrated that in random mixtures of 10 compounds in DMSO, the probability of a reaction occurring between two of the mixture's components is 26%. This value can be reduced by careful selection of mixture components (e.g. separating acids from bases) to approximately 9%.

4.2.3 Hardware and Automation

Automation is a requirement if libraries containing a large number of compounds are to be screened. Technology has been developed that allows the automation of almost all steps of the NMR screening process from sample preparation through to data analysis. The general setup for NMR screening consists of a robot for just-in-time preparation of each sample, which is then transferred to the magnet either through a flow system or as discrete samples on a rail system. There are several disadvantages in using a flow system, including the possibility of contamination of samples by previously screened compounds, the capillary line can be blocked if the protein or ligands precipitate or form aggregates, recovery of the sample is more laborious because it has been diluted, and cryoprobe technology (discussed later in this section) is not yet available in the flow system. Many of these problems can be overcome by using the discrete samples with the rail system.

Data acquisition is easily automated and there are several software packages that will automate data processing for 2D spectra. The processing of 1D spectra automatically is reported to be less reliable because of the large solvent signal, and usually requires manual adjustment of phasing. One of the most laborious tasks in NMR screening is the analysis and comparison of the resulting spectra. For 1D ligand-observed experiments, difference methods (e.g. STD) provide the most reliable method for interpretation of results, in that the presence of signals in the spectra will correspond to the ligands that are binding. In 2D protein-observed experiments (e.g. $^{1}H/^{15}N$ HSQC), a more statistically rigorous analysis of changes in chemical shift is required and a discussion of this is beyond the scope of this chapter.

Currently, approximately 50 to 100 samples can be screened per day and if mixtures contain 10 compounds each, this provides a substantial throughput. This throughput rate will increase as technology improves, as has been demonstrated by the use of cryoprobes. Cryogenic NMR probes, where the preamplifier and radio-frequency coils are cooled to low temperatures, can significantly increase the signal-to-noise ratio of an NMR spectrum. By use of these probes NMR data can be obtained in much faster times and by use of lower protein concentrations, which subsequently increases throughput, the total amount of protein needed to screen a library is reduced. For example, Hajduk and coworkers demonstrated the substantial improvements made through the use of a cryoprobe instead of a

conventional probe in $^{1}H/^{15}N$ chemical-shift perturbation screening. Stromelysin (50 μM) was screened against mixtures of 100 compounds (50 μM each), facilitating the screening of more than 10 000 compounds in one day. The use of lower concentrations of both protein and ligands increases the stringency levels for the binding strength of ligands. At a protein/ligand concentration of 0.5 mM, ligands with dissociation constants in the millimolar range can be detected, although at a protein/ligand concentration of 50 μM, this dissociation constant limit is reduced to approximately 0.15 mM. Although using higher protein/ligand concentrations can be advantageous when screening libraries containing small low affinity ligands, a higher stringency is required when screening large libraries, to reduce the number of hits obtained to a manageable number.

5 Conclusions

In this chapter, we have given an overview of the two major approaches used in NMR and drug discovery, structure-based design and NMR-based screening. Both areas are flourishing and, together with more traditional uses of NMR, they demonstrate the versatility of NMR as a tool in medicinal chemistry. The power of NMR has been dramatically enhanced over the last decade by developments in both instruments and methodology. On the instrumental side, increases in magnetic field strengths and the development of cryoprobes have greatly increased sensitivity. Linkages of NMR to LC and MS have increased versatility. On the methods front, there have been a range of new approaches discovered, which will enhance the study of larger molecular complexes. Advances in protein expression and labeling have played a major role in stimulating the development of new NMR pulse sequences to extract information from such complexes.

Keywords

Antigen Presenting Cell
Cells, including macrophages, B cells, and dendritic cells that take up and process an antigen into a peptide fragment capable of being presented by an MHC class II molecule on the cell surface.

Major Histocompatibility Complex Class II
Present peptide antigen to T cells.

Major Histocompatibility Complex Class II Binding Site
The region of a superantigen that recognizes and binds to MHC class II molecules.

Pyrogenic Exotoxins
A group of superantigens produced by the gram-negative bacteria *Streptococcus pyogenes*.

Staphylococcal Enterotoxins
A group of superantigens produced by the gram-negative bacteria *Staphylococcus aureus*.

Superantigen
A substance (as an enterotoxin) that acts as an antigen capable of stimulating much larger numbers of T cells than ordinary antigen.

T Cell
T lymphocyte; a cell bearing a T-cell receptor, which can control and mediate humoral immunity.

T-Cell Receptor
The receptor that enables the T cell to recognize and react to specific antigens.

T-Cell Receptor Binding Site
The region of a superantigen that recognizes and binds to the V_β elements of T-cell receptors.

Superantigens (SAgs) are a family of proteins produced primarily by *Staphylococcus aureus* and *Streptococcus pyogenes*. These toxins acquired the name *Superantigen* due to their ability to hyperstimulate the immune system. SAgs are not recognized by the immune system in the same way as conventional foreign proteins, and interact in a unique fashion with major histocompatibility complex (MHC) class II molecules and T-cell receptors (TCRs). Once formed, the trimolecular complex induces vast

T-cell proliferation resulting in massive cytokine release, epithelial damage, capillary leak, and hypotension. Recent additions to the family include toxins produced by *Mycoplasma arthritidis* and *Yersinia Pestis*. SAgs are implicated in several diseases including toxic shock syndrome (TSS), scarlet fever, and food poisoning; their function appears to be primarily to weaken the host sufficiently to allow disease to take hold.

1 Introduction

Conventional antigens: peptide fragments derived from exogenous proteins are displayed on the surface of antigen presenting cells (APC) by major histocompatibility complex II (MHC) molecules. These peptides are then recognized by circulating T cells and an immune response targeted toward that particular peptide is initiated. In contrast, superantigens (SAgs) are not processed by APC and remain as fully intact proteins. Structural evidence shows SAgs to bind to APCs on the external face of the MHC class II molecule and concomitantly to T cells via the external face of the T-cell receptor (TCR) V_β element. In contrast with the specificity that results from TCR binding to one particular type of conventional peptide antigen, interaction between SAg and the V_β element of the TCR supplies a much broader range of specificity, as whole subsets of T cells displaying the same V_β types are able to recognize the SAg.

Superantigenic toxins are very stable proteins. They are highly resistant to proteases, denaturation from heat and extreme pH, and are often found in food that are high in protein, salt, and sugar. In order to cause food poisoning, they must be able to survive not only cooking and preserving procedures, but also the digestive process.

2 The Superantigen Family

In order to be classified as an SAg, a toxin must demonstrate the ability to stimulate T cells in a V_β specific manner. The number of bacterial SAgs or proteins highly homologous to known SAgs has grown considerably over the last decade so much so that an international nomenclature committee for staphylococcal SAgs have described an international procedure for the naming of newly described SAgs and putative SAgs.

The staphylococcal enterotoxins (SEs) A, B, C1–3, D, E, H, I, and J toxic shock syndrome toxin-1 (TSST-1) were originally designated enterotoxins because of their emetic property when ingested. Since 2000, several new ''SEs'' have been discovered on the basis of sequence alignments, though it is proposed that none should be classified as SEs until it is demonstrated that they induce emesis after oral administration.

Along with the staphylococcal enterotoxins, the streptococcal pyrogenic exotoxins (SPEs) A, C, and H; streptococcal mitogenic exotoxin (SME)-Z_2, and streptococcal superantigen (SSA) produced by *Streptococcus pyogenes* represent the most well-characterized bacterial SAgs. Other pathogens, such as *Mycoplasma arthritidis* and *Yersinia pseudotuberculosis* have also been shown to secrete superantigenic

proteins. For the most part, this review will focus on the staphylococcal and streptococcal SAgs, with some discussion on the emerging SAgs from *M. arthritidis* and *Y. pseudotuberculosis* (*Mycoplasma arthritidis* mitogen – MAM and *Yersinia pseudotuberculosis* mitogen – YPM), as well as the wealth of putative SAgs uncovered by genomic initiatives. Broadly speaking, staphylococcal and streptococcal SAgs can be grouped into four subfamilies on the basis of amino acid sequence and three-dimensional structure: The first group is made up of the staphylococcal enterotoxins SEA, SED, SEE, SEH, SEI, and SEJ; both staphylococcal and streptococcal toxins form the second group, which consists of SEB, SEC1-3, SpeA1-3, SSA, and SEG; the third group contains streptococcal pyrogenic- and mitogenic toxins SpeC, SpeJ, SpeG, SpeH, SME-Z, SME-Z_2, and streptococcus dysgalactiae-derived mitogen (SDM); the SAg-like proteins SSL and TSST-1 form the fourth group. MAM and YPM have no sequence or structural homology to the rest of the bacterial SAgs and cannot be grouped with any of these subfamilies.

2.1 Molecular Architecture

Comparison of the three-dimensional structures of staphylococcal and streptococcal SAgs reveal a conserved two-domain architecture (Fig. 1). The two domains, known as the N- and C-terminal domains, are separated by a long solvent-exposed α-helix, spanning the center of the molecule. Typically, the N-terminal domain contains many hydrophobic residues in its solvent-exposed regions and structurally it has a significant similarity to the oligosaccharide/oligonucleotide binding fold (OB-fold) found in other proteins. In spite of this similarity, SAgs have not been seen to bind to either DNA or carbohydrates. The C-terminal domain resembles the β-grasp motif and is composed of a four-stranded β-sheet that is centrally capped by a long α-helix. Several SAgs also contain a highly flexible disulfide loop. Located in the N-terminal domain (Fig. 1), this flexible loop is implicated in the emetic properties of the staphylococcal and streptococcal toxins, as mutations of the two cysteine residues that form at the base of this disulfide loop abolishes the ability of these toxins

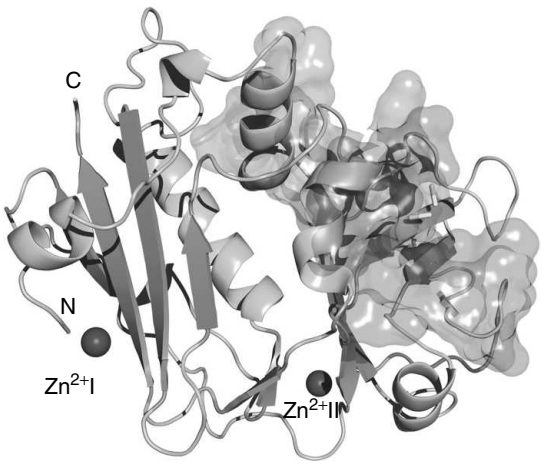

Fig. 1 Ribbon diagram of staphylococcal enterotoxin A (SEA), representative of the common structural features of the staphylococcal and streptococcal SAg family. Blue spheres represent the positions of the two zinc sites. The cysteine residues that form the disulfide loop are shown in stick representation (yellow), the surfaces defining the TCR binding region (green), and MHC class II binding region (red) are shown (see color plate p. xlii).

to induce vomiting in primates. Additionally, this loop has also been implicated in T-cell stimulation for several members of the staphylococcal and streptococcal SAg family.

2.2 Nonclassical Superantigens

The staphylococcal SAg-like proteins SSL5 and SSL7 also show the common architecture preserved among these related groups of proteins. This group of proteins is most closely related to TSST-1, although none of the SSLs have demonstratable superantigenic activity, and as such are linked to the SAg family purely due to sequence identity and structural homology. Differences between the SSLs and classical SAgs include extended secondary structure elements, extended loop regions, and differences in charge distribution over the protein surface. At present, it is not known whether these features have any biological significance.

The discovery and characterization of SAgs from bacterial sources such as *M. arthritidis* and *Y. pseudotuberculosis* have extended the topology of the family even further. MAM and YPMa show no structural homology to the rest of the SAg family whatsoever. MAM is composed entirely of α-helices, arranged in two domains to form an L shape. The N-terminal domain consists of four α-helices and a 25-residue N-terminal loop that wraps around the four-helix bundle, whereas The C-terminal domain contains six α-helices. YPMa is much smaller than the classical staphylococcal and streptococcal toxins (14 kDa), and consists of a jelly-roll fold comprising two β-sheets, each containing four antiparallel strands. Similarly, the structure of YPMa is, unlike any other known SAgs, structurally similar to viral capsid proteins.

2.3 The Immune Response to Bacterial Superantigens

Superantigens primarily target $CD4^+$ T cells, leading to a T-helper type 1 (Th1) response and no Th2 response. A dominant Th1 response causes the suppression of antibody production, which in turn reduces the clearance of the invading microbe, allowing disease progression. The resultant release of a variety of cytokines in high quantities from macrophages and T cells cause many of the symptoms associated with Sag-related disease, and eventually leads to hypotension through capillary leak. The array of cytokines produced include IL-1 and TNF-α from macrophages and TNF-β, IL-2, and IFN-γ from T cells. Most cytokine expression is transient and occurs within 12 h of SAg exposure, whereas signals involved in proliferation such as DNA synthesis and IL-2 receptor expression do not occur until over 24 h after toxin exposure. Once cells have undergone DNA synthesis, they are capable of re-expressing cytokines prior to a second round of proliferation.

3 Binding to MHC Class II Molecules

MHC class II molecules possess two separate binding sites for the classical staphylococcal and streptococcal SAgs. The first, a low-affinity binding site that is also known as the *generic site* is located on the α-chain of the MHC class II molecule (Fig. 2), whereas the second, a high-affinity zinc-dependent site is located

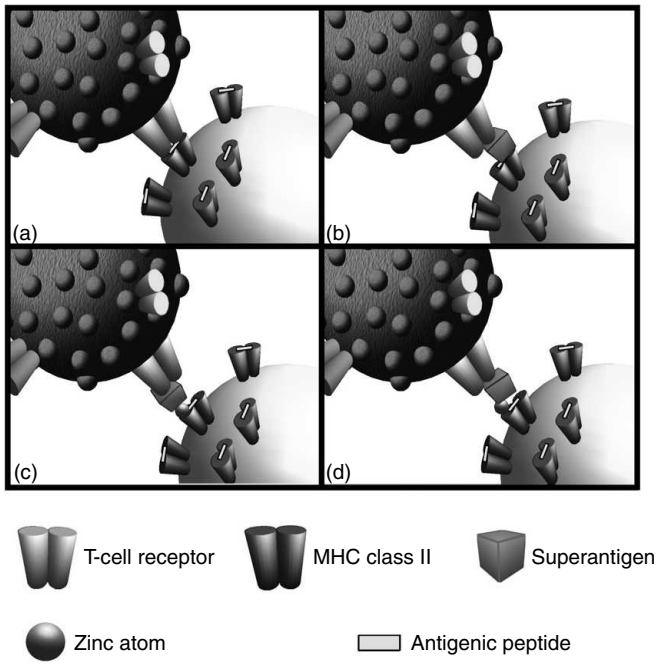

Fig. 2 Schematic representation illustrating the differences between conventional peptide antigen presentation and SAg presentation to MHC class II and T-cell receptors. (a) Conventional antigen is processed by the antigen presenting cell and displayed as discrete peptide fragments within the peptide binding groove of MHC class II molecules, direct interaction occurs between TCR and MHC II molecule; (b) SAgs bind to the solvent-exposed face of the MHC class II molecule (α-1) via its generic site, forming a bridge between TCR (Vβ) and MHC class II; (c) SAg binds to MHC class II (β1) via a bridging zinc atom in a high affinity, zinc-dependent manner; and interacts with TCR Vα as predicted for SEH; (d) SAg binds to MHC class II (β1) via a high-affinity zinc site, and interacts with TCR Vβ as is postulated for the remainder of the zinc containing SAgs. In both cases, the MHC class II molecule associated antigenic peptide has been shown to influence T-cell recognition of SAg/MHC class II molecule.

on the β-chain. SAgs bind via this high-affinity site approximately 100 times more strongly than to the generic site. A great deal of structural and mutational data has revealed that a range of diversity exists within the SAg family for binding to MHC class II molecules. Each SAg binds to different alleles of class II molecules to varying extent. While most of the SAgs, including TSST-1, SEB, and MAM bind preferentially to HLA-DR alleles, SAgs, such as SEC, SpeA, and SSA bind predominantly to HLA-DQ alleles.

3.1 The Generic Binding Site and the MHC Class II α-chain

X-ray crystallographic studies on SEB and TSST-1 in complex with the MHC class

II molecule HLA-DR1 via the low-affinity generic site, SpeC in complex with HLA-DR2, and SEH in complex with HLA-DR1 via the high-affinity zinc site have yielded a great deal of structural information about the binding of SAgs to MHC class II molecules. The SEB– and TSST-1–HLA-DR1 complexes demonstrate that both SEB and TSST-1 have similar binding modes to HLA-DR1. Interaction between HLA-DR1 and these SAgs mainly involves the α-chain of the DR1 molecule and the solvent-exposed, hydrophobic core at the N-terminal domain of the toxin. Similar hydrophobic ridge regions exist in several other SAgs and form the generic MHC class II binding site. One feature seen in the TSST-1–HLA-DR1 complex, (but not in the SEB–HLA-DR1 complex) is the number of additional contacts between TSST-1 and the peptide antigen displayed by the HLA-DR1. Indeed, truncating the C-terminal end of the antigenic peptide significantly affects TSST-1 binding to MHC class II molecules in mice.

3.2 Zinc-dependent Binding to MHC Class II β-chain

Several of the bacterial SAgs, with the exception of SEB, TSST-1, SSA, SSL1-, and YPM, have one or more zinc binding sites (Fig. 1). Zinc ions have been shown to play two distinct roles in SAg function. First, they act as dimerization sites, second, they have been shown to be important for the recognition of the MHC class II β-chain. SEA possesses a high-affinity zinc binding site in its C-terminal domain; this site has a substantially higher affinity for DR1 ($K_d = 100$ nM) compared with the generic binding site ($K_d = 10\,\mu$M), and if the two binding sites coexist, a K_d of 13 nM is observed. The importance of both of these sites is demonstrated by the fact that mutation of residues in either of these sites abolishes the toxin's ability to induce cytokine expression. The coexistence of these two distinct MHC class II binding sites may enable it to form a trimeric SEA–MHC–SEA complex, a phenomenon that has been observed in solution. Several other SAgs including SEE possess identical zinc ligands, and a similar case for SAg–MHC–SAg complex formation can be argued. Both SED and SpeC possess analogous zinc binding sites to SEA. In SED, the zinc ion acts as a means for toxin dimerization; SED can form zinc-dependent homodimers, whereas SpeC forms zinc-independent homodimers. Both SED and SpeC bind to the β-chain of MHC class II molecule by a zinc-mediated mechanism similar to that of SEA, and because of the ability of these toxins to dimerize, formation of trimers and/ or tetramers is a possibility. A similar binding mechanism has been proposed for SEH, SME-Z, SME-Z_2, SpeG, and SpeH, all of which lack a generic MHC class II binding site. This high-affinity zinc site, present in SEA is not seen in SEC or SpeA. Instead, a separate zinc binding site (with an estimated K_d of approximately 1 μM) is seen at the N-terminal domain of these toxins. In a similar fashion to the SEC-like zinc binding site, this secondary zinc binding site is also important for MHC class II binding (Figs. 1 and 2). Direct observation of zinc-mediated SAg–MHC class II complexes such as those seen in the crystal structures of SEH–HLA-DR1 and SpeC–HLA-DR2, have enabled a detailed analysis of these interactions. A great deal of similarity exists between the two complexes. The interactions between both SAgs and their MHC class II molecules are governed by a tetrahedrally coordinated zinc ion. For SpeC, three of the

coordinating ligands are from the toxin, and for SEH, two are from the toxin and one is from a water molecule. In both complexes, the fourth ligand is provided by residue His81 of the β1 chain of the class II molecule. In a similar fashion to the TSST-1-MHC class II complex, interaction between the SAg and the antigenic peptide is observed. Up to one-third of the contact area between SAg and MHC class II is taken up by antigenic peptide. In both cases, a majority of the interactions occur with the backbone atoms of the peptide, enabling both SpeC and SEH to have similar interactions with the antigenic peptide even though the composition of the peptide differs in both complexes. This would suggest that although the antigenic peptide plays an important role in the complex interaction, MHC class II binding is not entirely peptide specific.

To confuse matters further, another zinc binding site has recently been discovered in SEC2. This zinc ion is located near the generic MHC class II binding site and is thought to act as a site of dimerization for SEC2. If this zinc ion does indeed allow dimerization of SEC2, the generic MHC class II site would be blocked by the dimer interface; thus, MHC class II binding would be governed by the SEC2 primary zinc binding site. As a result, SEC2 would be able to bind to MHC class II molecules as a zinc-mediated dimer. SpeA1 and SpeC are also capable of forming homodimers, although in this case the mechanism is zinc independent. SpeA1 has recently been shown to exist in a disulfide linked dimeric form via cysteine residues located within the flexible disulfide loop, whereas the SpeC dimer is formed by direct interaction of the surfaces that usually form the generic MHC class II binding site.

Zinc was also thought to play a similar role in MAM, namely, binding to MHC class II molecules and toxin dimerization. However, the absence of zinc in the crystal structure of dimeric MAM in complex with HLA-DR1 suggests that zinc fulfills neither role. Clearly, the exact role of zinc in the action of this novel SAg requires further investigation.

Despite the MAM_2–HLA-DR1 complex bearing no immediate likeness to that of other bacterial SAgs, there are some similarities in the overall mechanism of interaction. Complex formation does not induce any major structural changes at the binding interface, which is consistent with other SAg–MHC class II complexes. The MAM_2–HLA-DR1 complex is formed through interaction of the N-terminal domain of MAM and a number of regions of HLA-DR1. Contact with the antigenic peptide (hemagglutinin peptide) in the peptide binding groove of the HLA-DR1 molecule is again observed. Interestingly, the MAM binding site on HLA-DR1 also overlaps the generic binding site for staphylococcal and streptococcal SAgs. In support of this, both SEB and TSST-1 have been shown to block MAM binding to MHC class II molecules. Moreover, MAM binding is also disrupted by those SAgs that bind to the high-affinity zinc site, as the MAM binding site on MHC class II also includes the region on the MHC β-chain, which contains His81. Although the crystal structure reveals MAM to bind to MHC class II molecules as a dimer, both monomer and homodimers are shown to be present in solution, indicating that MAM may be able to act on MHC class II molecules as both monomer and dimer.

Current understanding of SAg structure and function suggests that there is an increasing range of mechanisms by which SAgs can interact with MHC class II molecules. Although differences exist

between SAgs, three main binding modes are observed: (1) through zinc-mediated interaction; (2) via the generic site; or (3) as a homodimer, which can be either zinc or nonzinc mediated. In addition, it is also possible that a combination of any of these three mechanisms may be employed.

4 Binding to the T-Cell Receptor

In comparison to their interaction with MHC class II molecules, the binding of SAgs to T-cell receptors is at first sight a much more localized interaction. SAgs were thought to bind exclusively TCR via the TCR V_β element through a universally similar mechanism, where the binding is mediated by interactions between the side chains of the SAg and the backbone atoms from the V_β region. This results in each SAg selectively expanding T-cell subsets bearing certain V_β elements, while excluding others.

4.1 General Mechanism of Binding for Classical Superantigens to T-Cell Receptor V_β Elements

The TCR binding sites of the staphylococcal and streptococcal SAgs consist of comparable scaffold regions within which specific amino acids affect the V_β specificity. The binding site is formed by a shallow groove between the two domains of the molecule (Fig. 1). The structures of SEB, SEC2, and SEC3 in complex with TCR V_β seem to support this simple binding mechanism, a majority of the contacts between SAg and TCR are between the amino acid side chains within this groove and backbone atoms of the TCR V_β elements. The main interactions are between the side-chain atoms of the SAg and complementarity determining regions 1 and 2 (CDRs 1 and 2), and hypervariable region 4 (HV4) of the V_β chain. Close examination of the TCR binding sites of SEC2/3, SEA, and SEB indicate that an invariant asparagine residue (Asn23 in SEB/SECs; Asn25 in SEA) is essential for direct interactions with the TCR, and if this residue is mutated, T-cell stimulation is lost. This residue is located on the surface of the toxin, and is thought to have similar interactions in all the SEs. Mutagenesis studies have revealed that further interaction exists between SAg and TCR, which are conserved among many of the staphylococcal and streptococcal SAgs, including SEC1-3, SEB, SpeA, and SSA. In addition to this ''common core'' of residues, the differences in TCR affinity among the SAgs can be accounted for by several residues unique to each toxin. For example, the type of residue at position 26 of SEC2 confers specificity between SEC1, SEC2, SEA, and SEB via its interaction with Gly53 from the V_β chain. Similarly, the residue at position 91 of SEC2 is also implicated in TCR binding and is not conserved in SEA or SEB. By switching several residues for a dissimilar group of amino acids, a decreased affinity for certain V_β chains and an increase in affinity for others may occur. This is likely to be as a direct result of an increase in the amount of unfavorable interactions for one V_β element followed by an increase of favorable interactions for another V_β element. Experiments with SEA support this idea. SEA specificity for TCR is thought to be governed by three residues at position 21, 206, and 207. Exchange of these three residues for the homologous residues in SEE causes a change in the profile of the responding

V_β elements to that of the profile normally seen for T cells stimulated by SEE. It has also been shown that those residues that define the specificity of an SAg for particular V_β elements make the greatest energetic contribution to the overall stability of the SAg–TCR complex, and as the above evidence shows, these residues are comparatively few in number.

More recently, the two SAg–TCR V_β complexes SpeA1–V_β 8.2 and SpeC–V_β 2.1 have indicated that TCR binding, for at least some SAgs is not as simple as first thought. The interaction of SpeA1 with the TCR β-chain is similar to that of SEB, with several of the important contacts preserved. In addition, SpeA1 has an extra five hydrogen bonds with the TCR V_β compared to SEB. Thus, the mechanism of TCR binding employed by SpeA1 is slightly more intricate than those employed by SEB and SEC2/3. The complexity increases still further with SpeC; this toxin was found to bind to significantly more V_β residues than SEC2/3, SEB, or SpeA1, including numerous interactions with both main-chain and side-chain atoms of the TCR β-chain. The increased amount of contacts are most likely due to the deeper and broader cleft between the two domains of SpeC compared with other SAgs, as this is where the TCR binding site is located. Structural similarity between SpeC and TSST-1 mean that although the TCR binding site of TSST-1 is not yet fully characterized, it is likely that it shares similar binding characteristics. The available mutagenesis data suggests that the TCR binding site of TSST-1 is located in a similar position to SpeC, between the two domains of the toxin.

Both MAM and YPMa have been shown to bind to the TCR β-chain, although in the absence of a crystal structure of their complexes, the exact location and composition of their TCR binding sites are speculative. Clearly, more work needs to be carried out to determine the binding mechanisms of these novel SAgs before a direct comparison can be made to the staphylococcal and streptococcal toxins.

The characterization of SAg–TCR complexes have demonstrated that multiple modes of TCR interaction exist. The first, a high specificity binding mode, involves many contacts by both backbone atoms and side-chain atoms over an increased area as demonstrated by SpeC. This mode has high affinity for relatively few TCR V_β elements. The second, a moderate specificity mode, has fewer interactions over a reduced contact area. This mode has a modest affinity for a larger group of TCR V_β elements, such as seen in SpeA1. The final mode, a promiscuous binding mode, such as is seen in SEB and SEC2/3, suggests that binding to TCR V_β chains for these SAgs is a matter of simple conformational dependence.

4.2 Binding to the T-Cell Receptor Vα Element

The discovery that SEH, in contrast to all other SAgs, stimulates T cells in a V_α specific fashion, completely lacking any V_β expansion, adds further complication to the scheme. It is suggested that SEH may bind to TCR in a V_α specific fashion due to its presentation by MHC class II molecules via a zinc atom. Whether other SAgs that are presented to TCR by MHC class II in the same way can bind to V_α in the same way is yet to be established.

5 Formation of the Trimeric Complex for Signal Transduction

The complex course of events at the cell surface that lead to the formation of the MHC II–SAg–TCR complex is still ambiguous. It is possible for SAg to exist as monomer and dimer, and many SAgs have multiple MHC class II binding sites enabling them to form complexes with more than one MHC class II molecule or TCR. In terms of trimeric complex formation, this means that even further diversity exists in the ability of these toxins to interact with the immune system.

When considering complex formation, it is important to first consider the nature of membrane-bound receptors. In order for a complex to form, cell membranes need to be in close proximity to each other, and the receptors must diffuse to the site of interaction. It has been shown that in order for superantigenic T-cell activation to occur, a comparatively low percentage (<0.3%) of the MHC class II molecules must be occupied by the SAg. Higher concentrations of bound toxin result in an aborted T-cell response after a few cell divisions due to apoptosis. Thus, a low local concentration of MHC class II molecules on the cell interface is preferable for optimum superantigenicity. It is thought that the binding of a SAg to TCR induces clustering of the TCRs on the cell surface and the acquirement of the intracellular components required to transduce a signal. This is thought to occur in a manner that mimics peptide antigens with regard to receptor clustering, either through direct clustering events as proposed by the TCR oligomerization model, or by the binding of SAg homodimers to multiple MHC class II molecules, which in turn would promote T-cell clustering. Molecular modeling suggests that signal transduction stimulated by SEA through large-scale assembly is limited to four or five TCR–(DR1β-SEA-DR1α) tetramers, and requires the dimerization of MHC class II molecules. While TCRs would be clustered together in this model, TCR dimerization is thought unlikely. SEA is not unique in its ability to form zinc-mediated dimers. SED and SEC2 can form zinc-dependent homodimers, whereas SpeA1 forms a nonzinc mediated disulfide linked dimer; a SpeC dimer is also formed in the absence of zinc. MAM has also been shown to be able to form zinc-dependent and zinc-independent dimers, and YPM is thought to be able to form zinc-independent trimers. Clearly, SAgs have evolved slightly different ways of inducing receptor clustering. SAgs that act as monomers and possess only a single MHC class II binding site appear to rely on the interactions of the TCR V_α and MHC class II-β1, which increases the stability of the ternary complex to within the range seen for conventional antigen. A stable MHC–SAg–TCR complex with an extended half-life may therefore assist receptor clustering.

6 Roles of Superantigens in Disease

It should be noted that the association of an SAg with a certain disease does not mean that it necessarily causes the disease. In some cases, the presence of a microbe known to produce an SAg has been correlated with the disease. In other cases, expansion of a certain V_β subset is interpreted as evidence of the involvement of SAg in a disease. A definitive confirmation of the involvement of

an SAg requires the cloning of the putative SAg and its subsequent testing in an animal model. Thus, the involvement of SAgs in disease is established for relatively few conditions: these include toxic shock syndrome (TSS), food poisoning, Kawasaki disease, and scarlet fever.

6.1 Toxic Shock Syndrome

TSST-1 is the main causative agent for TSS and induces most of the symptoms associated with the disease in experimental animals. TSST-1 is responsible for nearly all cases of menstrual TSS, and approximately 60% of nonmenstrual staphylococcal TSS. The remainder of the cases can be attributed primarily to other SEs including SEB, SEC, and SEA, whereas SpeA is associated with most cases of streptococcal TSS. Although the exact nature of the disease is not fully understood, it is clear that toxic shock is in part a result of the superantigenic nature of these toxins. Superantigenicity and massive T-cell proliferation affect the cardiovascular system by causing extensive epithelial damage, capillary leak, and a decrease in peripheral vascular resistance resulting in shock as well as affecting kidney and liver function. The ability of TSST-1 to cause both localized or systemic symptoms in this manner dictates that it must be able to transverse the epithelial barrier. At present, the mechanism by which it is able to do this is unknown, but could include either passive diffusion, or cellular receptors. The ability of TSST-1 to cross epithelial barriers, if it exists, would make it unique among the SAgs. The use of a cellular receptor would require some kind of specific interaction with TSST-1, and therefore a receptor binding site. Structural evidence for such a binding site on TSST-1 is limited, and is confined to the observable structural differences between TSST-1 and the other SAgs. These differences include the lack of an α-helix in the C-terminal domain, the long N-terminal extension, and the absence of a disulfide loop. TSST-1 also has unique patches of hydrophobic and neutral residues on the front and rear of the β-barrel at the N-terminal domain. It is possible that a combination of these features could produce a receptor specific binding site in order for TSST-1 to traverse epithelial cells and allow systemic shock.

6.2 Staphylococcal Food Poisoning

Staphylococcus aureus is the leading cause of microbial food-borne disease in the world. Symptoms of staphylococcal food poisoning (SFP) include abdominal pain, nausea, vomiting, and diarrhea and are usually experienced within 2 to 6 h of ingestion. Little is known about how the physical properties of SAgs relate to the symptoms of emesis and diarrhea. It has been suggested that the symptoms of food poisoning are a result of high cytokine levels. Indeed, the side effects of IL-2 therapy often mimic those of SFP. More recent work indicates that the emetic properties of these toxins are not completely correlated with their superantigenicity. Several areas in the N-terminal region of SEA have been identified that are important for both emetic and superantigenic function. Carboxymethylation of histidine residues in SEB was found to abrogate emetic activity but still induce T-cell proliferation, indicating that the two activities are separate. The areas of the toxin that induce emesis and diarrhea are also thought to be

separate, because intravenous administration of a C-terminal fragment of SEC1 was found to induce diarrhea but not emesis in primates. The disulfide loop is considered to be one of the main regions responsible for emesis. Investigation has shown that the disulfide bond itself is not an absolute requirement for emetic activity, but the conformation within or adjacent to the loop is important for emesis. Further analysis of these toxins is required in order to assess the contribution of certain amino acids to the overall pathology of SAgs in the context of the diseases they cause.

6.3 Autoimmunity

The action of SAgs as immunomodulators has identified them as possible candidates for autoimmune disease. Since they do not discriminate between autoimmune and normal lymphocytes, SAgs would be able to stimulate autoreactive T cells, both locally and systemically. Although SAgs have not yet been directly implicated in human autoimmune disease, there is evidence to suggest their involvement. For example, SED-reactive T-cell lines have been shown to stimulate autoantibody production by B cells. Superantigens have been shown to be associated with a growing list of autoimmune conditions, including multiple sclerosis, arthritis, diabetes, and Kawasaki disease. Whether SAgs act as the initial trigger for autoimmunity or as external factors changing an ordinary controllable illness into an autoimmune condition for susceptible individuals, both remain possible, and clearly further work is needed to assess the roles of these toxins in this type of disease.

systems, such as low-frequency motions, by filtering out the nonessential components such as high-frequency motions. This type of study is very useful when coping with very large systems, especially when the computers are not powerful enough to sample all the biological timescales.

Cryogenic Electron Microscopy
A low-resolution experimental technique that measures structures of macromolecules. The resolution of the technique is usually not high enough for establishing atomic coordinates, but it can provide rough shapes of molecules. It is an effective way of getting the structures of supramolecular complexes that are usually hard to form diffracting crystals for X-ray crystallography.

Fiber Diffraction
A low-resolution experimental technique that measures structures of long filamentous fibers. The technique made a critical contribution in elucidating double-helical structure of DNA in the early stage of the field of molecular biology. In recent years, aided by the modern synchrotron radiation, the method is gaining momentum in studying many biologically important fibers such as F-actin filaments.

Large Conformational Change
Biological macromolecules fulfill their functions in a dynamic fashion. Motion is an integral part of function. Large conformational changes are large structural rearrangements that alter physical properties of protein complexes such as their affinity to their ligands or their ability to catalyze biochemical reactions. These changes can take place at different levels of structural components, which can be a localized loop, a single domain, or entire quaternary arrangement of the complex.

Molecular Dynamics Simulation
A computer simulation technique that maps the spatial and temporal trajectories of protein movement by numerically propagating Newton's equations of motion for all atoms in biologically relevant environment. It is widely used for studying dynamics of biological molecules.

Normal Mode Analysis
A simulation algorithm that decomposes motions of proteins into a set of orthogonal harmonic modes, which serves as a complete basis set from which any arbitrary vibration can be expressed as a linear combination. Mathematically, it is an eigenvalue problem. Usually, low-frequency modes are more biologically relevant. In recent years, normal mode analysis and other related algorithms have been shown to be very effective in modeling large-scale conformational changes, especially those of supramolecular protein complexes.

Structural Refinement
A computational procedure that optimizes the structural model against experimentally measured data by, for example, minimizing certain target functions that define the difference between the two.

Supramolecular Protein Complexes
Large protein assemblies that are formed by multiple subunits, or polypeptides, usually arranged in a unique quaternary architectural style to carry out specific biological functions. Such complexes are frequently seen in higher species due to higher level of complexity in regulatory mechanisms. The particular architecture is usually designed to accommodate the required structural motions involved such as those in allosteric proteins. Sometimes, supramolecular complexes are also referred to as *molecular machines*.

Many important biological functions are carried out by supramolecular protein complexes, which are characteristically formed in a hierarchical arrangement. For those complexes, just like large man-made structures, flexible motions are essential for maintaining robustness and for fulfilling their functions. To study the motion, various computer simulation techniques have played an important role in elucidating spatial and temporal trajectories of proteins. Furthermore, in recent years, computational modeling has also dramatically contributed to the improvement of structural models in refinement. In this chapter, to give a representative illustration of the subject, the author outlines several examples taken from recent studies of supramolecular protein complexes.

1 Architectural and Motional Characteristics of Supramolecular Complexes

Just like all kinds of natural or man-made structures, proteins are built in a modular fashion. The smallest structural modules for proteins are likely the individual globular domains that may fold relatively independently. Many proteins have more than one domain. In large assemblies, multiple subunits are organized in a hierarchical way to form the complexes. The size of complexes varies dramatically ranging from relatively simple dimers to huge multicomponent complexes such as viral particles and cytoskeleton filaments. Functionally, structural complexity is often related to the level of sophistication of regulation mechanisms in different organisms. In lower species, a particular biological function is carried out by smaller proteins, while, in higher species, it may be carried out by larger complexes with increased complexity in regulation.

There are evolutionary advantages for building large complexes in a modular fashion. By doing so, nature only needs to ensure the folding ability of relatively small sets of modules (often small domains) that act like building blocks, and then to optimize the outer shape of those modules to fit into the assemblies. In fact, using shape as an additional parameter for diversifying complex structures is a way by which nature achieves its vast architectural complexity via only 20 types of amino acids. Moreover, nature follows only a few design principles that are also commonly employed in man-made structures. For

example, shape complementarity among different protein subunits is common for ensuring the overall integrity of complexes similar to what is observed in the domes of ancient bridges and cathedrals.

Another important issue regarding complex structures is flexibility. Similar to large man-made structures, flexibility plays an important role in maintaining robustness of complexes and in fulfilling their functions. Many large molecular complexes behave just like man-made machines, for which motion is an integral part of functions. In general, a particular type of architecture is designed not only to ensure structural integrity, but also to optimize the coupling of motions among various interacting parts so as to transmit the actions from one part to another, for example, allosteric mechanisms.

As a consequence of the hierarchical nature of complex structures, typical molecular motions in supramolecular complexes are hinged domain movements. This is likely because these kinds of movements are energetically easier to move a whole chunk of structure around some flexible hinges so as to avoid substantial disturbance of the inner folding cores of each building block, which might have been evolved separately. In that sense, the conformational dynamics of the supramolecular complexes is somehow simpler in terms of their topological changes (although very large in scale) in comparison with folding in which all intricate side-chain placement needs to be satisfied. For the same reason, the motions of supramolecular complexes often follow some universally similar rules. Understanding a few representatives will enormously enlighten the understanding of many of them.

The best way to understand the role of protein conformational motions is to study the pathways of these motions and systematically map out the intermediate states they experience along the pathways. However, protein conformational motions are relatively fast, and the intermediates along the pathways are transient. They are usually very difficult to be captured by experimental methods. To overcome such a difficulty, state-of-the-art computer simulation techniques have made it possible to study the transient motional features in a reasonably accurate fashion. In particular, the power of computational investigation has been repeatedly demonstrated in numerous cases when the methods are combined with the experimental data. Outstanding contributions have been made for understanding dynamic functions of supramolecular complexes, and particularly to assist structural refinement for experimental measurement.

In the following sections, we will outline several examples taken from recent computational studies of supramolecular complexes. The purpose is not a comprehensive review; rather, it is a representative illustration to give readers a general overview of the subject.

2 Simulating Supramolecular Complexes at Multiresolution and Multilength Scales

2.1 State-of-the-art Simulation Methods

A large portion of biomolecular functions involves structural dynamics, which occurs in a wide range of length scales, for example, from vibrations of small chemical bonds to global conformational changes of supramolecular complexes. Meanwhile, experimental structural data are only available in varying resolution scales. In some

cases, one has high-resolution atomic coordinates by methods such as X-ray crystallography, but in others, one only has low- to intermediate-resolution density maps by, for example, cryoelectron microscopy (cryo-EM). To cope with such a wide-range scale distribution of biological dynamics, computer simulations have been playing an increasingly important role in providing a spatial and temporal framework for interpreting experimental observations.

Molecular dynamics (MD) simulation is a widely adopted method for studying dynamics-related properties of proteins. The essence of the method is to numerically propagate Newtonian equations of motion for all atoms in time so as to generate a trajectory in space from which all the dynamic properties can be computed. For studying supramolecular complexes and their associated large-scale conformational changes, certain types of modifications to standard MD simulation have been developed. One of the typical methods is the targeted molecular dynamics (TMD) method. Together with a few related versions such as steered molecular dynamics (SMD), they are widely used in modeling large-scale conformational changes. The basic idea for all these methods is the constrained simulation. Usually, the input of those simulations would be the two static end-point structures of a conformational change determined by X-ray crystallography. Then the dynamic pathways between the two end-point structures can be simulated by slowly ''guiding'' the simulation from one state to the other. The methods are approximate, but they have been demonstrated to be very effective in delivering a trajectory from which biochemical data can be rationalized and, more importantly, further experimental probes can be designed to verify the suggested mechanisms.

Another effective way of analyzing molecular motions is harmonic modal analyses. The most commonly used ones are normal mode analysis (NMA), quasi-harmonic analysis and its related version of essential dynamics. Mathematically, modal analyses are eigenvalue problems. The modes form a complete basis set, by which any arbitrary molecular deformational motions can be expressed as a linear combination. In general, modal analyses are particularly effective where elastic (harmonic) properties of molecules are concerned. The underlying principle for modal analysis is to study biomolecular functions by filtering out the less important high-frequency motions and focusing on the dominating low-frequency components.

Numerous examples have demonstrated that functionally important transition pathways of biomolecules, especially those of supramolecular complexes, often follow the trajectories of one or a few low-frequency normal modes. An important fact that emerged from those studies is that the protein structures have evolved in such a way that their intrinsic structural flexibility, as manifested in normal modes, facilitates the functionally important conformational variations. Moreover, in recent years, several important new algorithms have been developed. Among them, particularly important ones are the coarse-grained NMA methods. They have enabled one to simulate deformational motions of supramolecular complexes at dramatically extended resolution and length scales.

Most importantly, NMA methods have enabled structural refinement in several structural biology fields including fiber diffraction, cryo-EM (cryo-electron microscopy), and X-ray crystallography.

This is because the biological specimens intrinsically contain the information of molecular motions. Even in the most ordered crystal lattices, certain mobile components of molecules still present certain degrees of structural and motional anisotropy, which are often functionally related. Powerful computational methods are necessary to take those motional features into account in structural refinement. For supramolecular complexes, another difficulty comes from the lack of enough independent experimental observations that could lead to severe overfitting if too many adjustable parameters are used for refinement. Using harmonic modal analysis to aid refinement can significantly ease such a problem.

2.2 Biological Applications

In this section, we will briefly outline several typical examples for modeling large-scale motions of supramolecular complexes. The first one is molecular chaperonin GroEL with available atomic coordinates. Another one is human fatty acid synthase (FAS) based on low-resolution electron density maps from cryo-EM measurements. And the final one is F-actin filament based on a model established from fiber diffraction. Those examples cover a wide range of length scale and resolution scale. Other examples in literature include ribosome, viruses, and so on.

2.2.1 Molecular Chaperonin GroEL

Chaperonin GroEL is a huge molecular complex that facilitates protein folding in bacterial cells. Its architecture consists of two cylindrical rings with seven identical subunits arranged in a back-to-back fashion with a dyad symmetry (see Fig. 1). In the middle of the complex, there is a central channel that can drastically alter its size as a consequence of large allosteric conformational changes of the complex driven by the binding of ATPs, the heptameric cochaperonin GroES, and nonnative polypeptides. Essentially, the central cavity plays a role as a cage in one of the two rings, the so-called "Anfinsen Cage," for facilitating polypeptide folding in a protected environment.

The static X-ray structures of different conformational states of the GroEL complex elucidate the end points of conformational changes. But they do not provide information of pathways for the transition. This information has to be supplemented by computational simulations. Two major types of simulation methods have been applied. One is NMA and the other is TMD simulation.

In NMA of GroEL, the study revealed intrinsic flexibility of each individual subunit that plays a vital role in its structural response to ATP binding. It was shown that two dominating low-frequency modes could capture the essential features of ATP-driven conformational changes, which include the downward motion of the intermediate domain and upward motion of the apical domain. NMA also captured the twisting motion of the apical domain that was later shown to be essential for facilitating protein folding.

The results of NMA were later corroborated by a more detailed TMD simulation performed from the close state to the open state. The TMD trajectory revealed the sequence of events in time along the transition pathway (which was missing in NMA) (see Fig. 2). More detailed atomic interactions between key residues were also observed. The results suggested that the intermediate domain, especially the M helix, has to come down first to close the binding site of ATP, which is important for hydrolysis. Then the large-scale upward motion of

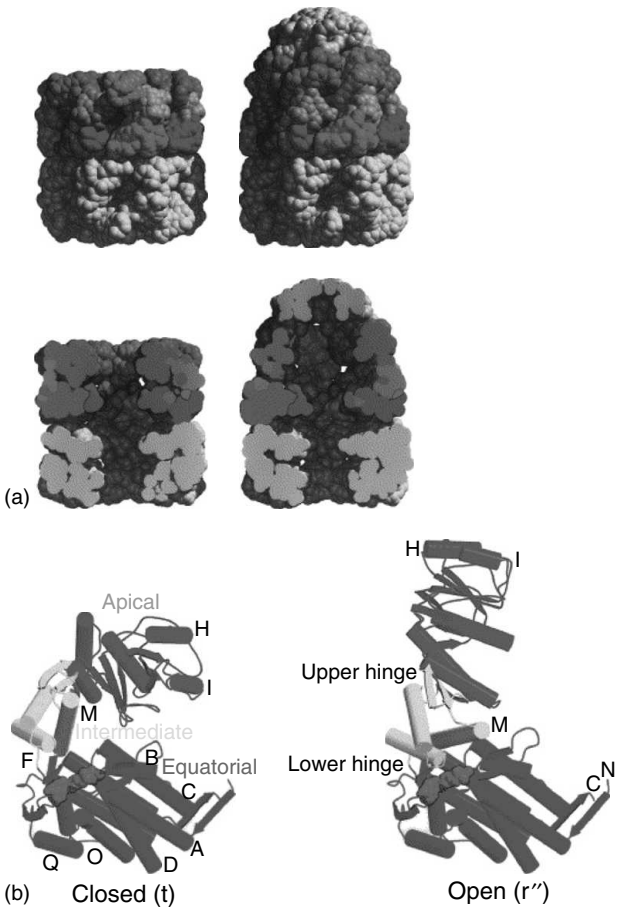

Fig. 1 The overall architecture and conformational change of GroEL. The closed ATPγS crystal structure, and the GroEL–GroES–$(ADP)_7$ structure are shown from left to right. (a) van der Waals space-filling models (6 Å spheres around C atoms). Upper panels show the overall dimension; lower panels show the interior of the complex by a cut-through view. Different colors are used to indicate the subunits in the upper ring. The domains are distinguished by shading: apical, medium hue; intermediate, light hue; equatorial, dark hue. The lower ring is uniformly in yellow and GroES is uniformly in gray. (b) Representations of a subunit of GroEL corresponding to the structures is shown in (a). The color code is: apical, green; intermediate, yellow; equatorial, red. The nucleotide is shown as a blue space-filling model. Some of the key secondary structural elements are marked. The view of the subunits is roughly from inside out of the GroEL central cavity. This figure was modified from Ma, J., Sigler, P.B., Xu, Z., Karplus, M. (2000) A dynamic model for the allosteric mechanism of GroEL, *J. Mol. Biol.* **302**, 303. (See color plate p. xli.)

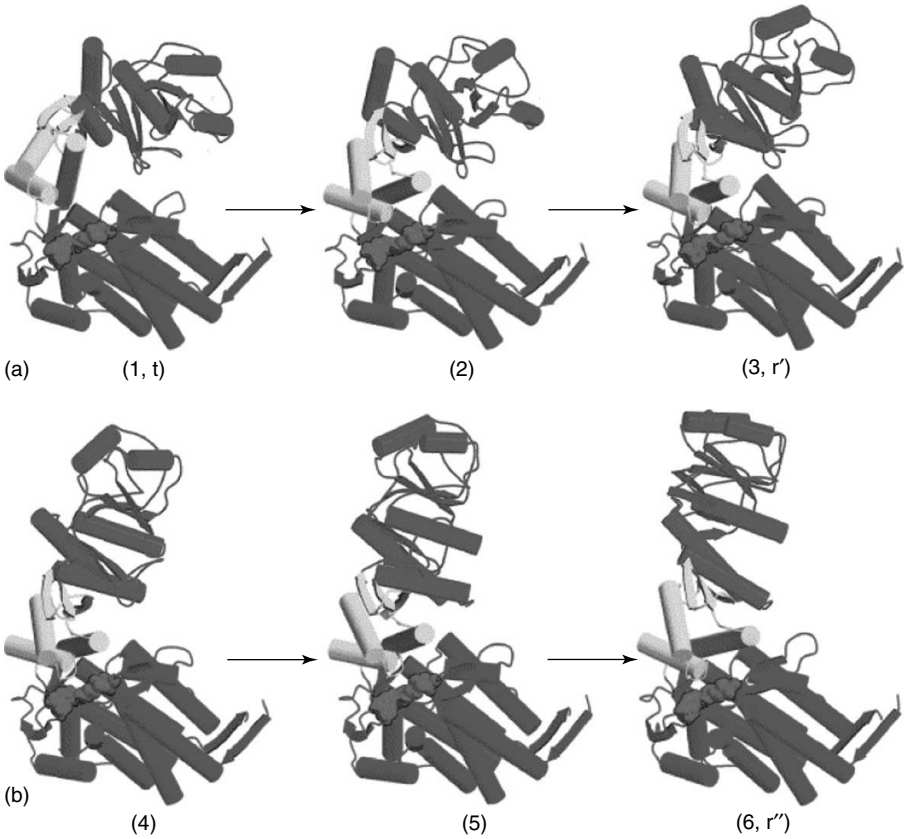

Fig. 2 Calculated transition path. (a) Schematic representation of the two-stage transition. (b) A set of structures on the path: (1) through (3) correspond to the first stages associated with nucleotide binding, that is, the t to r′ transition; (4) through (6) correspond to the second stage involving GroES binding, that is, the r′ to r″ transition. Structures (1) and (6) labeled t and r″, respectively, are the X-ray structures. The other structures are from the TMD simulation. The equatorial domain is superimposed as a reference in the various structures and so it has an essentially fixed orientation. The view of the subunit is the same as that of Fig. 1(b) and the twist of the apical domains, especially in the second stage, is toward the reader. This figure was adapted from Ma, J., Sigler, P.B., Xu, Z., Karplus, M. (2000) A dynamic model for the allosteric mechanism of GroEL, *J. Mol. Biol.* **302**, 303.

the apical domain follows. The transition is completed by a nearly 90° twist of the apical domain so that the chemical nature of the inner wall of GroEL central cage changes from hydrophobic in the close state to hydrophilic in the open state, which plays a determining role for GroEL-assisted protein folding. In addition to the transition pathways, the computational results also provided rational evidence for the allosteric mechanisms of GroEL, which has positive cooperativity within a ring and negative cooperativity between two rings.

2.2.2 **Fatty Acid Synthase (FAS)**

FAS catalyzes the synthesis of long-chain saturated fatty acids – palmitate, from acetyl-CoA, malonyl-CoA, and NADPH. In

animals, including humans, the catalytic centers of FAS involve an acyl-carrier protein (ACP) and seven catalytic enzymes. All of them are covalently connected together in a single polypeptide chain encoded by a single gene. The native FAS is a dimer of two identical subunits and each monomer has a molecular weight of 272 000 Da. The homodimer, essential to the functions, is arranged in a head-to-tail fashion forming two active catalytic centers. The 3D structure of FAS was determined by cryo-EM technique to about 19-Å resolution (see Fig. 3).

FAS is a multidomain complex with a very unique nonglobular quaternary arrangement. Much like many other multidomain supramolecular complexes, structural flexibility is one of the central issues in the function of FAS. In particular, domain movements of FAS are likely to be essential for facilitating the multistep catalytic reactions of the synthesis of palmitate. Although the traditional textbook view of FAS mechanism is such that the long and flexible (20-Å maximal length) phosphopantetheinyl moiety of ACP carries the substrate from one active site to the other, there are growing lines of biochemical evidence showing that the flexibility of the enzyme may also be involved in shuffling the substrates.

To computationally investigate the flexibility, the NMA method based on cryo-EM density map was applied to the 19-Å density maps of FAS to compute the patterns of thermal deformational motions. The most significant simulation results were that there are two types of major flexible hinges in the dimeric structure of FAS. One is an inter-subunit hinge located at the small inter-subunit connection (Fig. 4a,b). The other is an intra-subunit hinge located at the relatively thin neck region (Fig. 4c,d). Thus, a FAS dimer has one inter-subunit hinge between two subunits and two intra-subunit hinges from two subunits.

The patterns of the low-frequency deformational modes demonstrated that the domain movements of FAS around these hinges are primarily rigid-body movements. In the very lowest-frequency mode (mode 7), the motion is primarily around the inter-subunit hinge (Fig. 4a). Each subunit moves as a rigid body and the dimer undergoes a see-saw-like bending around the twofold symmetry axis in the pseudo-plane of the dimer. Biologically, one may regard such a motion to be the one that can transiently alter the width of the cleft by, for example, bringing domains in the opposite subunit closer, which would be advantageous in facilitating the elongation of fatty acyl chain between the cysteine sulfhydryl

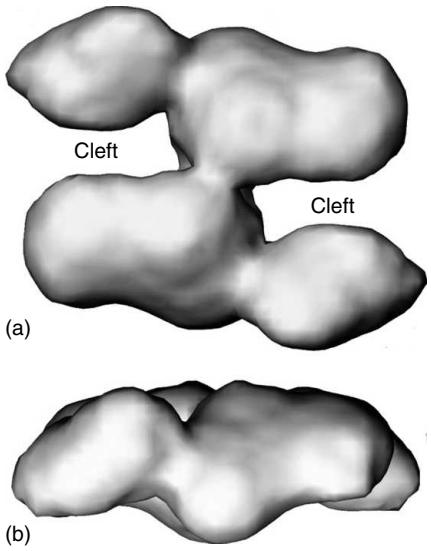

Fig. 3 The electron density maps of FAS determined by cryo-EM at 19-Å resolution. Only the one with a twofold symmetry imposed in the reconstruction is shown. The top one is a top view and the bottom one is a side view. The clefts between subunits are labeled.

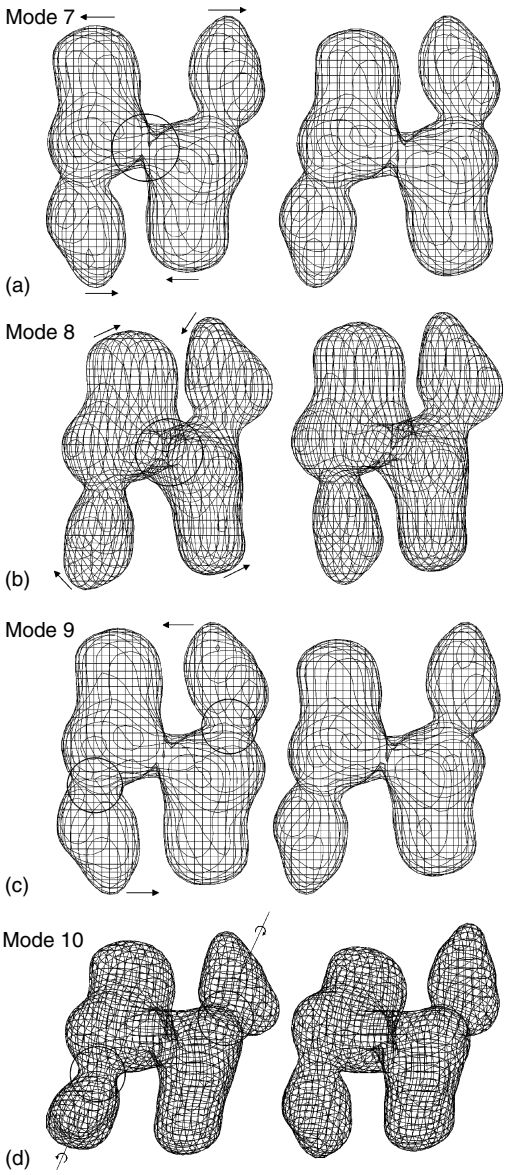

Fig. 4 The motional patterns of the first four lowest-frequency deformational modes: mode 7(a), 8(b), 9(c), and 10(d). Note, the first six modes are zero modes corresponding to global translation and rotation of the entire molecule. For each mode, two opposite conformations (left and right) during harmonic vibration are shown to illustrate the direction of the motion. The amplitude of the motion was arbitrarily chosen for visual clarity. The arrows are used to indicate the directions of the motions. The larger circles in (a) and (b) indicate the inter-subunit hinge and the smaller circles in (c) and (d) indicate the intra-subunit hinges. The dotted lines in (d) indicate the longest axes of the subunits. This figure was adapted from Ming, D., Kong, Y., Wakil, S.J., Brink, J., Ma, J. (2002) Domain movements in human fatty acid synthase by quantized elastic deformational model, *Proc. Natl. Acad. Sci. U.S.A.* **99**, 7895.

group of condensing enzyme and the phosphopantetheine sulfhydryl group of ACP. Early biochemical study showed that the two sulfhydryl groups from two opposite sides of the catalytic reaction centers could be cross-linked by a disulfide bond quickly. This fact indicates that the two sides are in direct proximity – an event that can presumably take place via large domain movements similar to what is described in normal modes.

Besides the very lowest-frequency mode, other low-frequency modes also revealed important domain movements.

For example, the second lowest-frequency mode (mode 8) describes an out-of-plane twisting between two rigid subunits around the inter-subunit hinge (nearly perpendicular to mode 7) (Fig. 4b). It is possible that this type of motion could bring together the subunits in two opposite catalytic reaction centers. The linear combination of modes 7 and 8 would facilitate the two subunits large-scale motions around the inter-subunit hinge. Similarly, the third (mode 9) (Fig. 4c) and fourth (mode 10) (Fig. 4d) lowest-frequency modes present the motions around the two intra-subunit hinges.

All together, the conformational motion of FAS can be regarded as the combination of these fundamental deformational modes. Although the dimeric FAS molecule has a chemically symmetric structure and the calculation was performed on the structure with a twofold symmetry imposed, the NMA clearly demonstrate that FAS is a highly flexible and heterogeneous molecule. Large-scale domain movements can take place in various directions, which results in a wide range of conformation of FAS. Biologically, those domain movements could be important for facilitating and regulating the entire synthesis by coordinating the communication between components of the structure, for instance, altering the distance between various active sites inside the catalytic reaction center. Finally, another important usage of the heterogeneous conformational distribution revealed in NMA is to improve the refinement in the cryo-EM reconstruction (see Sect. 3.1).

2.2.3 F-actin Filaments

Actins are filamentous protein complexes that are important for cell transport, cytoskeletal support, and contractile events in almost all eukaryotic cells. They exist in two forms. In nonionic solutions, the dominant form is a monomeric G-actin of 41 kD. In the presence of salt, G-actin monomers polymerize into a double-stranded helical polymer called *F-actin*, which is the functional form of actin. Structural information on several forms of actin includes the atomic coordinates of G-actin (Fig. 5a) and the Holmes model of F-actin filaments established from fiber diffraction. In the Holmes model, F-actin filaments appear to be formed by two right-handed long-pitch helical strands that twist around each other with a rise of 27.5 Å and

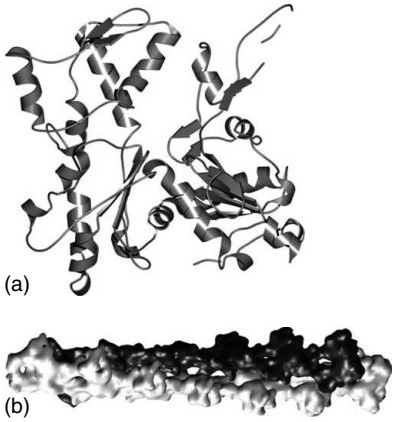

Fig. 5 Structures of actins. (a) Structure of G-actin monomer that contains 375 amino acids. (b) The Holmes model for a 13-subunit repeat of F-actin filament established from fiber diffraction with two helical strands differently colored. To illustrate the overall shape, the atomic coordinates were blurred to 8-Å resolution. This figure was adapted from Ming, D., Kong, Y., Wu, Y., Ma, J. (2003) Substructure synthesis method for simulating large molecular complexes, *Proc. Natl. Acad. Sci. U.S.A.* **100**, 104.

a rotation angle of -166.15° per monomer around the filament axis (Fig. 5b). The minimum repeat of the double-stranded helix contains 13 monomers (the 13-subunit repeat) and the total length of F-actin could be several microns or longer.

In recent years, a growing body of experimental evidence indicates that a large portion of dynamic properties of F-actin filaments, such as those modulating operations of molecular motors, is directly related to their intrinsic elasticity. A deep understanding of the mechanical elastic properties of F-actin filaments is, therefore, vital to elucidating their roles in motile and cytoskeletal systems.

Since the size of F-actin filament is way beyond conventional computational methods, a new method, substructure synthesis method (SSM), was developed to extend the computational capacity in simulating vibrational motions of very long filamentous systems. In SSM, a given molecular complex structure is regarded as an assemblage of substructures that can be chosen arbitrarily, and sometimes quite naturally, for example, as domains, subunits, or large segments of biomolecular complexes. One first computes a set of substructure modes by methods such as NMA to represent the motions of substructure, then, the motions of the entire structure are generated by linking the substructures together using a set of constraints to enforce geometric compatibility at the interfaces of adjacent substructures. For periodically repeating systems, a hierarchical synthesis scheme (HSS) can be employed in combination with SSM to rapidly achieve the desired complexity. Computationally, the efficiency of SSM comes from avoiding the full eigenvalue problem for the entire structure.

The procedure of SSM–HSS was applied to the synthesis of the vibrational modes of F-actin filaments of 4.6 μm from the modes of a single 13-subunit repeat. Figure 6 shows a few typical lowest-frequency bending modes. All of these modes move in a plane, which is a typical feature for a homogeneous elastic rod. Similar behavior was also observed for twisting and stretching modes. These results clearly suggest that one can use SSM–HSS to scale-up the microscopic dynamic information, obtained from atomistic simulations, to a wide range of macroscopic length scale.

In summary, the computationally synthesized vibrational modes for F-actin filaments by SSM–HSS provide an orthonormalized basis set by which any arbitrary elastic deformation of the filaments

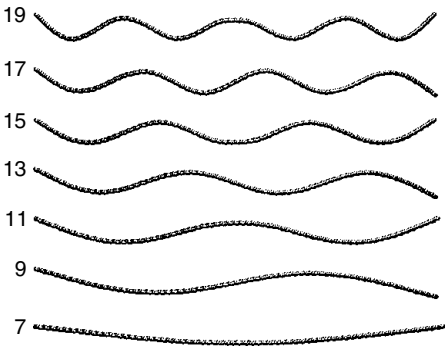

Fig. 6 The motional patterns of several lowest-frequency bending modes for the 4.6 – μm F-actin filament calculated by SSM–HSS. The indices of the modes are marked. The even indices are the ones that degenerate to the displayed one. The 7th mode is the lowest-frequency mode. This figure was adopted from Ming, D., Kong, Y., Wu, Y., Ma, J. (2003) Simulation of F-actin filaments of several microns, *Biophys. J.* **85**, 27.

can then be expressed as a linear combination. These modes can also be used to characterize the motions of F-actin filaments at a continuously varying length scale, that is, from the extremely localized high-frequency motions all the way to global elastic deformational motions. The bending motions are likely to dominate the motions of long filaments, while other types of deformations such as twisting and stretching are likely to be important to short-range local deformations of the filaments. Finally, the methods are equally applicable to other filamentous systems in cells, for example, tubulin, collagen, and DNA. A major application of these modes is in assisting structural refinement for fiber diffraction (see Sect. 3.2).

3 Refining Supramolecular Complexes at Multiresolution and Multilength Scales

One of the most important applications of NMA is in assisting structural refinement for large flexible systems. Since the low-frequency normal modes are collective parameters that describe the motions in a global fashion, the biggest advantage of using normal modes as refinement parameters is that only a very small set of modes are often enough to represent the motional features during refinement. Such an approach drastically cuts down the number of adjustable parameters needed for the refinement. Particularly in cases such as cryo-EM and fiber diffraction, there are not many independent measures due to low resolution, and a smaller number of parameters is always good for avoiding overfitting in refinement.

3.1 Normal-mode-assisted Cryo-EM Structural Refinement

Similar to X-ray crystallography and many other structural determination methods, the structural dynamics within the particle population due to the inherent flexibility of biomolecules can lead to smearing out of the cryo-EM averaging. At the current stage, only extraordinarily flexible systems have a realistic issue with conformational heterogeneity. But, in the near future, once the resolution of cryo-EM reaches a certain level, the conformational heterogeneity will become a major limiting factor for resolution of many systems. FAS is one of the systems that was currently influenced by the conformational heterogeneity in measurement. Although the actual data reached a much higher resolution, the final cryo-EM reconstruction for FAS was only at 19 Å. A computational strategy in conjunction with NMA was developed to separate the heterogeneous data such that structurally homogeneous particle images can be grouped to achieve higher resolution reconstructions within each group.

In the procedure of standard cryo-EM single model refinement, one first generates a set of projections of an initial 3-D model. After that, one aligns each raw particle image against each projection in 2D and groups the image with the projection it is most similar to. Once the alignment is done, average images are taken for the particles grouped with each projection. Such a procedure produces a class average from the raw particle data corresponding to each projection image. Finally, the class averages can be used to construct a new 3-D model, which is used to seed the next iteration of refinement.

In the normal-mode-based refinement of FAS, the initial models were established from the original structure and the two end-point conformers of the first two vibrational modes (modes 7 and 8 shown in Fig. 4a,b) were with an arbitrary amplitude. Totally, there were $n = 5$ initial models for the multirefinement algorithm (Fig. 7). The particles were classified, and in this case, one produced n class averages for each orientation, which could be used to produce n new 3D models to seed the next round of iterative refinement. The procedure also led to n subsets of the raw particle data associated with each of the 3D models. The results clearly showed that the conformational heterogeneity predicted by NMA were real in measured cryo-EM particle population.

Although with some degree of success, the normal-mode-assisted cryo-EM refinement has not become a general method for every system. One must overcome several technical difficulties in order for the method to become a routine structural refinement procedure. But the concept involved in normal-mode-assisted cryo-EM refinement harbors the hope for facilitating high-resolution structural determination by cryo-EM in the future. Twenty or thirty years ago, X-ray crystallography went through the same stage; sooner or later, cryo-EM will also reach a resolution range where molecular motions become a limiting factor for resolution.

3.2 Fiber Diffraction Refinement Based on Long-range Normal Modes

A very important application of long-range normal modes for biological fibers is in assisting refinement of structural models against data from fiber diffraction, which is an effective technique for studying filamentous systems that are ubiquitous in cell. Typical examples range from simple polypeptides, polynucleotides, and polysaccharides, to cytoskeletal filaments and filamentous viruses.

In the field of fiber diffraction, it has been known for a long time that long-range filamentous deformations may have significant contributions to the errors of the refined models. To cope with this problem, the atomic model of F-actin was refined against fiber diffraction data using long-range normal modes as adjustable

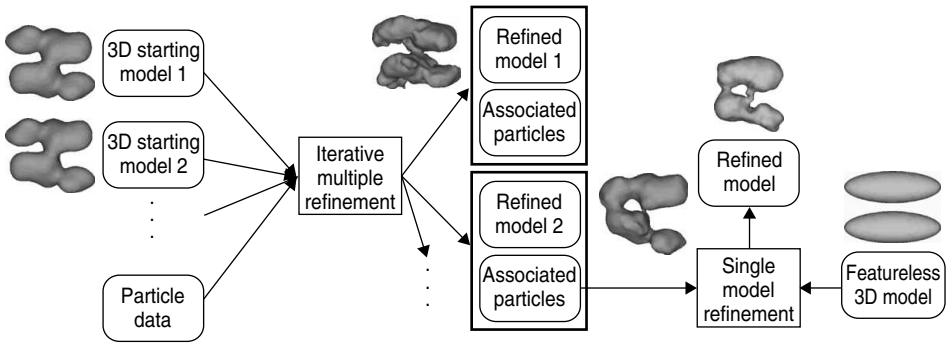

Fig. 7 A flow diagram of the second test used to verify that structurally consistent subpopulations were determined from the raw heterogeneous particle data set. A featureless model (right) was refined against the particle data used to generate refined model 2. The result of this refinement appears to be in the same structural substrate as refined model 2.

parameters to account for the collective long-range filament deformations. Each of the four domains of monomeric G-actin was treated as a rigid body to isolate the contributions of long-range deformations. The improvement in refinement was monitored by the drop in R- and R_{free}-factors using individual or combinations of modes calculated by SSM. It was found that the bending modes make the most significant contributions to the refinement. By including only ~7 to 9 bending modes as adjustable parameters, one was able to decrease R-factor for 2.4% (Fig. 8). This means that, for any fiber diffraction refinement, a substantial portion of errors is due to long-range deformations, in particular, because of the bending of the filaments. Therefore, the effects of these long-range deformations must be included in the refinement in structure determinations by fiber diffraction. Moreover, the advantage of SSM-based normal mode refinement is that it uses a small set of long-range modes as adjustable parameters to achieve a good fit, thus preventing the potential overfitting.

4 Discussions and Future Perspectives

For most of biochemical reactions in living organisms, what makes them different from the same reactions in test tubes is that biochemical reactions in cells are strictly regulated. They take place only when needed, to the required extent, and at the desired rate. Any malfunctioning in regulation of the reactions could result in

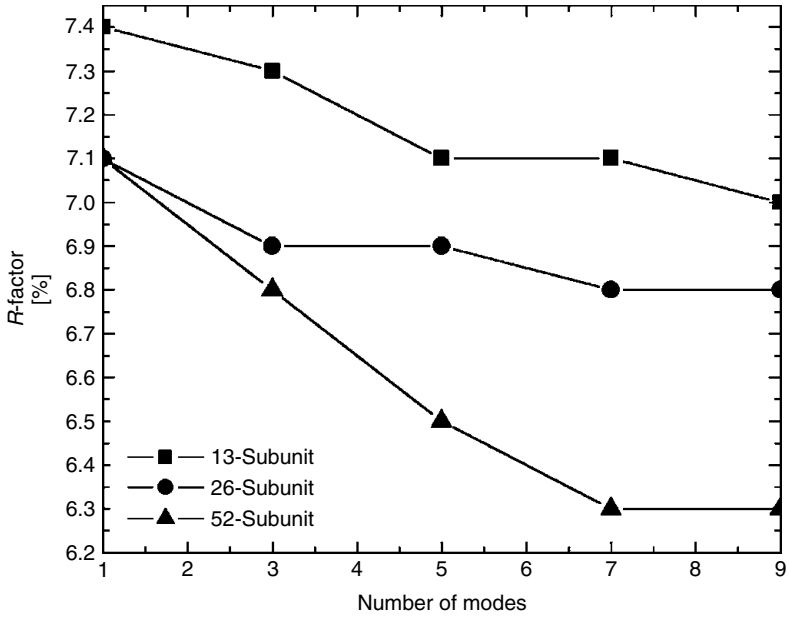

Fig. 8 Refinement results using various lengths of repeats as helical unit cells with a combination of multiple low-frequency normal modes. This figure was adopted from Wu, Y., Ma, J. (2004) Refinement of F-actin model against fiber diffraction data by long-range normal modes, *Biophys. J.* **86**, 116.

damage to the organisms by causes such as diseases. In most systems, especially supramolecular complexes, the regulatory mechanisms almost always involve large-scale conformational changes as the cases in allosteric proteins. Thus, understanding the structural and energetic nature of those conformational changes are vital for understanding biological functions.

As described earlier, the TMD and its related methods have played an important role in simulating large conformational motions. In recent years, the most dramatic success came from the widespread applications of coarse-grained NMA, which lies in the realization that, in modeling dynamics of large complexes, it is feasible to abandon the traditional concepts of protein structure (bonds, angles, dihedrals, etc.) and to treat the structure as an elastic object, whose shape and mass distribution can be obtained from electron density maps of the complexes, at various resolutions, from methods such as X-ray diffraction or cryo-EM. The directionality of the elastic deformational modes of the complexes can then be determined solely on the basis of low-resolution electron density maps. Numerous studies have shown that the patterns of those elastic modes match the biologically relevant conformational changes of proteins.

In the future, various biophysical methods will continue to be developed for studying dynamics of biological complexes. Of particular importance is to combine the computational methods with the experimental methods to iteratively elucidate the structures and mechanisms. This is exemplified by a recent ongoing study of the huge structure of nuclear pore complex by Sali's group at the University of California, San Francisco. A wide range of experimental data derived from all kinds of experimental methods, each providing partial and useful information regarding structure and dynamics, are gathered as constraints for computational modeling. As a consequence, a fairly accurate structural model can be established on the basis of experimental data from which no such model was possible by any conventional means. Here, the author would like to emphasize that the concept of utilizing limited, but diverse, experimental data as constraints to guide the computational modeling will play an increasingly important role in the future study of supramolecular complexes. This is because, for those large systems, no single technique can deliver a complete description of mechanisms.

Keywords

Fourier Transform (FT)
A mathematical technique capable of converting a time domain signal to a frequency domain signal.

Infrared (IR)Light
Electromagnetic radiation at wavelengths longer than the red end of visible light and shorter than microwaves (roughly between 1 and 100 microns).

Infrared Microspectroscope
An instrument that combines features of a spectrometer and microscope apparatus, providing an infrared spectrum for a small sample area of the specimen.

Microscope
An instrument that provides a greatly enlarged image of an object, allowing the viewing of features that cannot be seen with the naked eye.

Spectrometer
An instrument for analyzing a spectrum, that is, the intensity of radiation as a function of wavelength.

Synchrotron
A circular accelerator of charged particles, such as electrons. As the electrons accelerate around each bend in the ring, they are guided by powerful magnets and give off energy in the form of light.

Synchrotron Infrared Microspectroscopy is a powerful method for obtaining infrared spectrum of a small area of the specimen, using synchrotron light as the source. The brightness of the broadband synchrotron beam is 1000 times higher than that of thermal infrared sources, and allows analysis of sample areas down to the diffraction limit (e.g. 5 μm at 2000 cm^{-1}) at high signal-to-noise ratios in a short time. The technique is most widely used in biosciences, providing information on chemistry on microscales of virtually all biological specimens, like bone, plants, and other biological tissues. Some applications of the technique include infrared imaging of neurons subjected to various brain diseases, bone osteoporosis, biodegradation of man-made pollutants in plants, nutrition value of seeds, and protein folding in microsecond time regimes.

1 Introduction

Infrared (IR) spectroscopy measures intensity of the IR light at a particular frequency, providing information on the vibration of covalent bonds within molecules. The wavelengths of the IR light absorbed by a vibrating bond depend on the nature and type of the bond, the applicable selection rules, and the type of the vibration excited, and are also influenced by the inter- and intramolecular interactions of the molecules. The intensity of the light depends (as defined by the Beer–Lambert law) on the concentration of the vibrating molecules. Therefore, the IR spectrum furnishes information related to the quantity, composition, structure, and environment of the sample. Since the spectrum is additive, that is, all IR-active bonds present in the sample contribute to it simultaneously, a complete picture of the absorptions of functional groups is obtained, offering detailed information on sample chemistry.

IR spectroscopy has a number of advantageous features for the analysis of biological samples. Data acquisition can be quite rapid and dilute species can be detected. The method is also flexible, as samples can be examined in liquid or solid states without destruction of the sample, while instruments are widely available, reliable, and easy to use. Infrared studies of purified materials are quite straightforward. However, biological samples from tissues or cell preparations are both spatially and chemically heterogeneous. Probing samples with a beam size larger than the discrete spatial elements produces an average spectrum of all tissues probed by the beam, as the IR spectrum is additive. Without a sufficiently small beam, the discrete chemical species within discrete features of the tissue cannot be identified.

The device that focuses the infrared light onto a small spot is an IR microscope. The importance of the IR microscopy was realized early in the last century, but only during the last two decades has it experienced rapid development. Spatially resolved IR microspectroscopy can produce a two-dimensional array of spectra from which a chemical image (often called ''map'') is generated. Infrared microscopy has been utilized in various branches of sciences, including forensic approaches, materials science, art restoration, cell biology, and disease. Its advantage over a number of other spectroscopic techniques

is that it provides chemical information for multiple species simultaneously and directly on a micron scale without stains or contrast agents. Light microscopy can provide chemical information using specific chemical imaging agents, while X-ray techniques can be tuned to an absorption edge to probe specific elements. Magnetic resonance spectroscopy can also provide chemical information and has sensitivity similar to infrared, but submillimeter resolution is difficult. The high brightness of the synchrotron as an infrared source provides enhanced lateral resolution, faster acquisition times, and superior spectral quality. As a result, synchrotron infrared spectroscopy has flourished at the turn of the century, and a number of book chapters and review articles have been published. This chapter illustrates the potential offered by infrared microspectroscopy coupled with synchrotron radiation in biochemistry and biology.

1.1 Development of IR Spectrometers

The first IR spectrometers were equipped with monochromators, which select single wavelengths (or frequencies) of IR light and deliver them to the sample. The monochromator could be based on prisms or diffraction grating. These dispersive spectroscopes were slow and the observed source size limited the IR light that could be focused onto the sample such that spatial resolutions of less than 1 mm were impractical, even with elaborate beam condensers. The development of technology, especially in computers, brought the first interferometric spectrometers to the market. These developments changed not only the IR spectrometry in general but also made IR microspectroscopy possible.

Interferometric spectrometers are based on the Michelson interferometer schematically shown in Fig. 1. The IR radiation from the source is divided in half by a beamsplitter, usually a half-silverized mirror placed at 45° to the incident beam. The two halves of the IR beam further assume separate paths, each going toward one arm of the interferometric stage. One half travels toward a stationary mirror, and the other is directed toward a moving mirror. After the reflection, the two halves of the incident radiation recombine at the beamsplitter and again divide into two parts, traveling either toward the source or the sample (see Fig. 1). Only the half traveling toward the sample is used. If the mirror is moved at constant velocity, the two halves of the incident beam travel different pathlengths and the light reaching the sample, and ultimately the detector, is modulated in intensity due to constructive and destructive interference. The intensity of the light at the detector will vary sinusoidally, a maximum being registered each time that the retardation (i.e. difference of the pathlengths) is an integral multiple of the light wavelength λ. The plot of the intensity of the light versus retardation is called interferogram. Since retardation is also time dependent as the mirror moves at constant velocity, one obtains a single-beam IR spectrum by computing cosine Fourier transform of the beam intensity at the detector. The single-beam IR spectrum is a variation of the light intensity as a function of wavelength (or frequency) of the light. The abscissa of the IR spectrum is therefore inverse time, as the frequency is, by definition, the number of oscillations in unit time. A transmittance spectrum is obtained by dividing two single-beam spectra, one from an empty cell (background) and one with the sample. For traditional reasons, the abscissa of an IR spectrum is

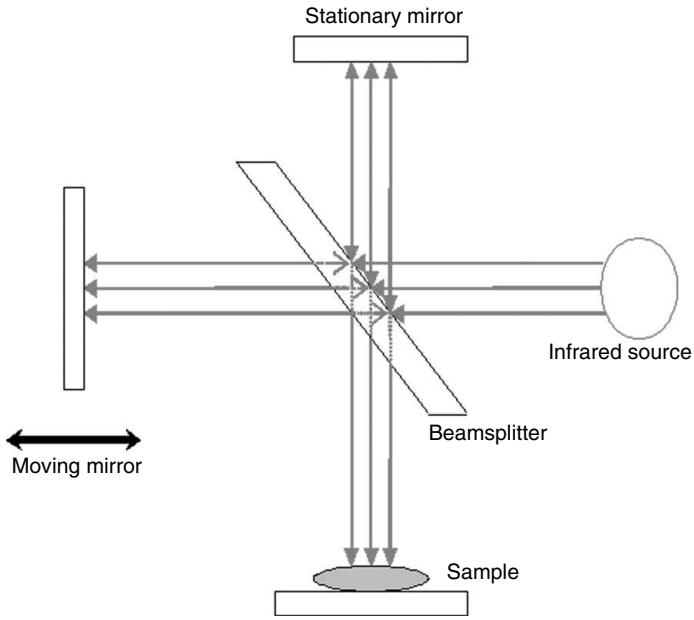

Fig. 1 Michelson interferometer, showing incident radiation coming from the source on the right onto the beamsplitter that delivers one half of the beam to the stationary mirror (a) and the other half to the moving mirror (b). After recombining the two half-beams, the modulated light is reflected toward the sample held by a substrate on the bottom.

usually plotted with increasing wavelength (in micrometers), or with decreasing wave numbers (reciprocal wavelength, in cm^{-1}), while the ordinate is given in absorbance (i.e. negative logarithm of transmittance) because the latter is directly proportional to the concentration of the sample by the Beer–Lambert law.

It should be realized that all frequencies of the incident light are going toward the two arms of the detector simultaneously, so that the intensity of the signal registered at the detector is the sum of all IR frequencies. The single-beam spectrum is produced by complex Fourier transform of the light intensity for all frequencies and all retardations. Fourier Transform Infrared (FTIR) spectrometers are able to compute the IR spectrum by the use of an algorithm for fast-Fourier transform (FFT), developed in mid-1960s. Along with the development of fast, low-cost computers required for the spectrum computation, other technical advances brought FTIR spectrometers into routine usage, ultimately replacing dispersive spectrometers. The ability to shine all wavelengths onto the sample simultaneously and deconvolve the discrete frequencies and the ability of the beamsplitter to accept greater input of radiation compared to a grating or monochromator are the major advantages of modern instruments (termed *Fellgett's and Jacquinot's advantages*, respectively). Additional advantages include optical verification of mechanical motion by interference fringes of a laser positioned parallel to the IR beam, and development

of fast and sensitive detectors that greatly enhanced sensitivity such as mercury cadmium telluride (MCT) detectors.

1.2 FTIR Microscopes

Infrared microspectroscopy provides information relating the spatial distribution of materials within IR suitable samples (described below) with the goal in biology to obtain spectra of individual tissue components. An infrared microscope is a beam condenser that reduces the diameter of the IR beam by focusing the light onto a small area. Even though the first commercial IR microscopy attachment was designed in the 1950s, it was not until the 1980s that it became a practical analytical tool, coinciding with the wider use of FTIR spectrometers worldwide. During the 1980s, IR microscopes became available for nearly all FTIR spectrometers. Stringent requirements are needed in the design of a microscope to achieve high signal-to-noise ratio with high spatial resolution. IR microscopes are available from a number of companies worldwide and their Web pages are given in the Bibliography section.

In design and operation, infrared microscopes are similar to the visible microscopes, except that their optics contain only mirrors rather than lenses, so that the IR light can pass through with minimal absorption. The IR light follows the same path as the visible light. Furthermore, modern IR microscopes can be equipped with a number of methods for better visualization of the sample, including polarized light, fluorescence illumination, or differential interference contrast imaging.

Although novel FTIR spectrometers and microscopes deliver high performance, often the practical limit of the spot size at the sample is tens of micrometers. This limits the applicability of the IR microspectroscopy when imaging single cells or tissues, as the subcellular structures relevant to biology or disease rely on imaging at the diffraction limit of light (5 μm at 2000 cm^{-1}). A synchrotron source allows the spot size to be reduced, because the synchrotron IR light is essentially diffraction limited and orders of magnitude brighter than thermal sources, as shown over twenty years ago. Most commercially available IR spectrometers and microscopes accept input from an external source, so that very little modification of the instruments is needed to adapt it to accept synchrotron light.

2 Synchrotron Radiation

2.1 Synchrotron Infrared Facilities Worldwide

Synchrotrons are facilities that produce high-flux electromagnetic radiation in a continuous spectrum from infrared through the visible and UV to the X-ray region onto a small spot. Generally, their operation relies on emission of radiation of electrons orbiting at a speed close to the speed of light (see Sect. 2.2). Because of the advantages of the synchrotron over thermal IR source (see Sect. 2.3), many synchrotron facilities around the world have at least one infrared beamline either in operation or planned. The list of the current operational and planned synchrotron infrared facilities is given in Table 1. Design and current research on infrared beamlines are reviewed in recent publications.

2.2 Production of Synchrotron IR Radiation

At the National Synchrotron Light Source (NSLS), electrons from an electron source are accelerated with a linear accelerator. Subsequently, they enter into a booster ring where they are further accelerated before entering a storage ring (see Fig. 2). Infrared radiation is delivered by the smaller of the two storage rings of NSLS, the VUV-IR ring. In this ring, the electrons are accelerated to energy of 800 MeV. The storage ring uses magnetic field to bend electron trajectory onto a closed orbit. Because the velocity of electrons is close to the speed of light, they give off the radiation in a relativistic manner at the end of each of these ''bending'' magnets. The radiation thus produced is directional, concentrated, free of thermal noise, and predominantly polarized. The highest current (1 A) is obtained immediately after the injection of electrons in the storage ring, and the current is allowed to decay over time to about 400 mA after several hours. In order to keep the average current around 750 to 800 mA, the storage ring is filled seven times in 24 h, with the fill interval of 4.5 to 5 h during the normal working hours, and 3 to 3.5 h during the remainder of the day.

2.3 Advantage of the Synchrotron Source

To obtain a good-quality spectrum, the intensity of an IR band must be at least 100 times greater than noise. Signal-to-noise

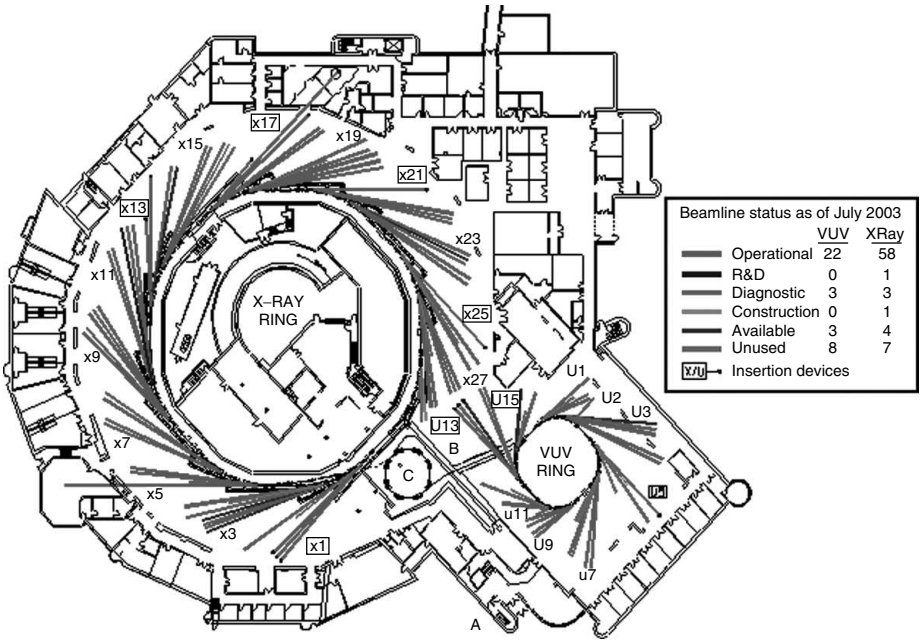

Fig. 2 Schematic diagram of the synchrotron facility at the National Synchrotron Light Source, Brookhaven National Laboratory, Upton, NY, showing the electron source (A), linear accelerator (B), and booster ring (C), as well as the VUV/IR storage ring and beamlines. The location of U2 port on which the Albert Einstein Center for Synchrotron Biosciences' U2B beamline is constructed is also shown.

ratio (S/N) is related to the ratio of source power (SP) that can be calculated for each source, and noise power (NP) that is characteristic of the instrument. Source power at a wavelength λ is directly proportional to the brightness $B(\lambda)$ of the light source. The source comparison of the synchrotron and globar sources was recently calculated. For a standard FTIR spectrometer with a globar source, SP and NP can be calculated to be about 4.5 mW and 0.1 nW respectively, for IR radiation at $\lambda = 2000\ cm^{-1}$ (5 μm) and one-second-long measuring time, so that S/N is 45 000. However, such a high S/N is obtained with the beam size at the sample no smaller than 0.6 mm. SP degrades rapidly when the spot size is reduced. For IR microscopy where spatial resolutions in micron scales are needed, $SP(\lambda)$ at a 5-μm spot size can be calculated to be only about 0.05 nW, so that $S/N = 0.5$. To obtain S/N of 100, the scan time would be about 11 h. Unrealistically long scanning time (1.5 months) is needed to achieve S/N of 1000.

A brighter source like synchrotron easily overcomes this difficulty. The advantage of the synchrotron lies in its brightness that is 2 to 3 orders of magnitude higher than that of globar sources. Brightness of a storage ring is given by the relation: $B(\lambda) = 75\ I\ BW/\lambda^3$, where I is the ring current and BW is the bandwidth. Using the parameters for the NSLS VUV-IR ring, one obtains $SP(\lambda)$ of 0.1 mW, so that S/N is about 1000 for one-second measuring time. By comparison, the synchrotron is an excellent source for infrared microscopy studies at spatial resolutions on the order of the wavelength λ. It should be noted that the source power of a synchrotron is directly related to the ring current (not the ring power), which explains why the NSLS VUV-IR ring, with a maximum current of 1 A, is the world's premiere facility for the infrared microscopy. The synchrotron infrared beam is nondestructive to biological samples, producing an average temperature rise of only 0.5 K to a test sample closely resembling biological materials.

2.4 U2B Beamline Microspectroscopic Instrumentation and Capabilities

The Albert Einstein Center for Synchrotron Biosciences' U2B beamline is located on the U2 synchrotron IR port of the VUV-IR ring of the National Synchrotron Light Source (see Fig. 2). The port delivers light in solid angle of about 80 mrad horizontally by 40 mrad vertically. The U2 extraction port chamber was installed in the VUV ring in December 1996. The mirror box that divides the light for the use of two equal-end stations (U2A and U2B) was installed in October 1997, and the remainder of the beamline in March 1998. After conditioning, it took full beam in May 1998. U2A and U2B end stations were then constructed, and each took light in November 1998. The U2B beamline has been in full operation and has been accepting outside users since the spring of 2000, after a commissioning period of one year.

The synchrotron beam is steered and focused by a combination of ellipsoidal and planar mirrors to provide a 1 : 1 image of the source. The beam passes through a series of valves and masks, then through a wedged diamond window into a mirror box where it is divided into two equal lines (U2A and U2B). The beam that is steered toward U2B beamline continues through a rough vacuum-pumped tube and then through a window (KBr or polyethylene, depending on the desired frequency range) into the nitrogen-purged instrumentation listed below. The total angular acceptance is 45 H X 40 V mrad.

The beamline is equipped with a dry nitrogen-purged FTIR spectrometer (Magna 860, Thermo Nicolet Instruments, Madison, WI, USA), a Nicolet NicPlan IR microscope, and a custom-made external cryostat chamber. The spectrometer is equipped with a Michelson interferometer having capabilities such as rapid scan, step scan, and the ability to accept external beams and utilize external detectors. For measurements in its internal chamber, a narrowband mercury–cadmium telluride (MCT/A) and a deuterated triglycine sulfate (DTGS) detector with polyethylene window are available, covering a range from 5000 to 100 cm^{-1}. The doubly confocal NicPlan IR microscope is outfitted with a full range of objectives, such as 10X and 20X visible objectives, a 32X IR objective (Thermo Spectra-Tech) for both transmission and reflection IR measurements, and an attenuated total reflection (ATR) ZnSe objective (Thermo Spectra-Tech) for reflection measurements of highly absorbing and/or thick samples. The microscope is capable of diffraction-limited spatial resolution. It is further equipped with a computer-controlled stage that brings the sample under the objective, and fully automated IR microscopic experiments are performed by Atlμs software (Thermo Nicolet) with the possibility to view the visual image of the sample together with its three-dimensional IR representation (IR map).

In order to broaden the range of vibrational spectra collected by the microscope, a flat pick-off mirror has been introduced in the optical path to allow the use of external detectors. The mirror directs the light either to the internal narrowband MCT/A detector operating in the 7000 to 650 cm^{-1} range, or to the external detectors. With the use of external detectors, the lower frequency limit of the spectra obtained through the microscope is extended, at the expense of the signal-to-noise ratio. Three detectors are placed behind the microscope: a liquid nitrogen–cooled broadband MCT/B detector (Belov Technology, New Brunswick, NJ, USA) operating in a 5000 to 450 cm^{-1} spectral range with a sensor size of 0.25×0.25 mm, a liquid helium–cooled dual-detector system (Infrared Laboratories, Tucson, AZ, USA) combining a silicon bolometer with a wedged white polyethylene window that covers the far-spectral range (650–10 cm^{-1}), and a Si:B photodetector with a KRS-5 window for measurements in the mid-IR (3500–350 cm^{-1}). The signal-to-noise ratio is the highest for MCT/A (3–8 times higher than MCT/B, depending on the frequency, while that of the Si:B photodetector is comparable with MCT/B around 600 cm^{-1}, though improved by about twofold to around 450 cm^{-1}.

With the use of the bolometer, the lower frequency limit is extended to about 30 cm^{-1}. A set of motorized and manual translation stages and collimating optics are placed behind the microscope to precisely align the external detectors. The complete optical path, from the spectrometer through the microscope and to the detectors, is continuously purged with dry nitrogen to insure a significant reduction in water vapor absorption that would otherwise render portions of both the mid-IR and far-IR unusable.

3 Experimental Aspects

3.1 Microscopic Sampling for Transmission Spectroscopy

A collimated beam from the synchrotron is directed onto the interferometer, which

modulates the wavelength of the light, and then is passed on into the IR microscope. Depending on the design of the microscope, the light can be delivered to the microscope's first objective either from the top or the bottom. In the case of the NicPlan microscope, at the U2B beamline, the light enters from the top. Before entering the first condenser, the light passes through a variable aperture that limits the illumination of the sample to the selected area. The schematic representation of the microscope in transmission and reflection modes is shown in Fig. 3.

In transmission mode, the IR light enters the first condenser that focuses the beam onto the sample and passes through the sample that partially absorbs the light. The nonabsorbed beam then passes through an IR window that holds the sample and is collected by a second condenser that recollimates the beam. To compensate for spherical aberration caused by the IR window (or windows), condensers are equipped by a variable compensation ring. If there is only one window beneath the sample, the compensation ring at the first condenser is set to zero, while that at the secondary condenser should be set to the thickness of the window. In the case when a sample is squeezed between two windows, compensation rings on both condensers should be set to the thickness of the window. To minimize light scattered from the sample, the IR light recollimated by the second condenser usually passes through another aperture on its path to the detector.

Windows for transmission spectroscopy should be less than 3 mm thick. Choosing a window depends on the frequency range desired, physical properties (e.g hardness, if sample needs to be squeezed between two windows), and chemical properties (e.g. solubility in water). Care should be taken if the sample was kept in an ammonium-based solution prior to sectioning and placing on the window, as many of these window materials can make complexes. The list of the common

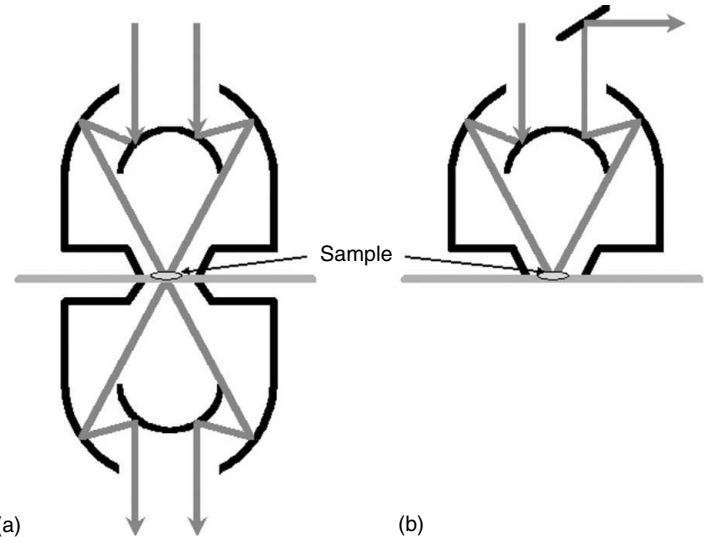

Fig. 3 Optical path of the infrared beam through Schwarzchild IR objective in (a) transmission and (b) reflection modes.

Tab. 2 Physical and chemical properties of some commonly used window materials for IR spectroscopy.

Window Material	*Transmission Range [cm^{-1}]*	*Properties: solubility in H_2O [g 100 cm^{-3}]*
CaF_2	4000–1100	Clear; 0.002
BaF_2	4000–800	Clear; 0.17
ZnS	4000–600	Clear; insoluble
ZnSe	4000–650	Orange; insoluble
KBr	4000–400	Clear, very soluble
KRS-5 (TlBr-TlI)	4000–200	Red; 0.05
Diamond	4000–50	Clear; insoluble; expensive

transmission window materials is given in Table 2. Most of these windows are also transparent to visible light.

3.2 Microscopic Sampling for Reflection Spectroscopy

The second most common way of collecting IR microspectra is in reflection mode. In this case, only about one half of the beam reaches the sample (see Fig. 3). The modulated IR light is sent through the top aperture and focused onto a small area of the sample by the first condenser. The portion of the light not absorbed by the sample reflects off the flat surface beneath the sample and passes through the same portion of the sample once again. The first condenser recollimates the light and sends it to the detector by a mirror. Since this mirror blocks 40 to 50% of the incident light, transmission mode is a preferred method for collecting microspectra because of the higher flux of the incident light on the sample. Furthermore, inhomogeneities in the sample may cause oscillations in the background of the reflection spectra. Because the beam passes through the sample twice, the thickness of the sample should be approximately half of that for the transmission spectroscopy.

Traditional substrate material on which the sample is placed is a highly polished metal slide that efficiently reflects IR radiation, for instance, gold. Recently, IR-reflective slides became commercially available at a fraction of the cost of the windows for transmission spectroscopy. They are made of a common glass slide on which an IR-reflective coating is deposited on one side. The reflective surface consists of several layers, comprising two silver coatings that reflect IR light, and a protective coating of SnO_2. One of the first vendors of these slides, Kevley Technologies named them low-e MirrIR. The slides are durable, insoluble in water and common organic solvents, and transparent for the visible light while reflecting about 95% of the IR radiation in the range 4000 to 400 cm^{-1}. Because of these properties, reflection spectroscopy recently became a very popular method for microspectroscopy.

3.3 Microscopic Sampling for ATR Spectroscopy

Attenuated total reflection spectroscopy is done on samples that cannot be cut into thin sections suitable for either transmission or reflection methods. An ATR

objective is a Schwarzchild IR objective that contains a small hemisphere made of an IR-transparent material, like ZnSe, Ge, or diamond. Since Ge is opaque for visible light, and diamond can be cost prohibitive, ZnSe is usually preferred. The objective has two masks. For viewing of the sample, the mask lets in radiation that is nearly perpendicular to the sample. During data collection, mask permits only radiation that enters the ATR hemisphere at near-grazing angles (65–80°), so that the rays are totally internally reflected back into the hemisphere. However, because of the nature of light propagation at the interface between two media having different refractive indices, the light penetrates into the sample via evanescent field. Penetration depth of the light is usually of the order of the wavelength (i.e. several micrometers), which is suitable for the IR measurements. The totally reflected light is then recollimated by the objective as in the reflection mode, and sent to the detector. Because the mask only allows beams that are close to grazing angle, a severe reduction in flux, up to 70%, is expected in the ATR spectroscopy in comparison to the normal reflectance mode.

In contrast to the microsampling discussed above, the thickness of the sample is not a factor in ATR spectroscopy. Although this technique involves very little sample preparation, it is not applicable in all cases. Since the sample needs to be in close contact to the ATR element to ensure a good-quality spectrum, the use of automated mapping methods cannot be done because ATR element and/or the sample may be damaged while the sample stage is moved. Samples must be either firm (like bone) or mounted on a stiff substrate. Care should be taken with soft samples as they may be damaged, and could also leave a residue on the ATR element, so that it would need cleaning before each data collection. Furthermore, the spectral region is obviously limited to the transmission range of the ATR element (see Table 2).

3.4 Microscopic Sampling for Grazing Angle Spectroscopy

Grazing angle spectroscopy is commonly used for probing very thin samples placed on a highly reflective surface. The surface-sensitive technique uses similar objective and mask as in ATR spectroscopy, and the IR light path is also similar. No ATR element is needed for grazing angle mode. The substrate is a highly polished, reflective surface and the sample is deposited directly on it. The thickness of the sample must be less than the wavelength of the IR radiation, to get a good signal with this technique, and because of the difficulty to cut such thin biological samples, this technique is rarely used.

4 Sample Preparation

The sample preparation of biological samples is possibly the most critical part of a successful IR microscopy experiment. Questions regarding stability or degradation of the sample, especially right after the removal from the body, fixation, imbedding into materials for sectioning, thickness of the samples for different IR microscopy experiments, and so on, need to be addressed before the actual sample preparation. Also, for the IR data to be biochemically relevant, the cells must be preserved in a lifelike state without introducing artifacts. A few general principles are outlined below.

If fixation of the sample tissue is desired to prevent possible degradation, formalin should be used rather than water/ethanol mixture, as ethanol causes proteins to aggregate. While formalin has less of a tendency to induce unfolding of proteins, the fixation should be done with low concentrations and washed with copious amount of saline fluid or deionized water before drying to prevent the formalin IR signatures in the spectra.

Tissue samples for IR microspectroscopy should be prepared in a similar fashion as for ordinary light microscopy. Although the optimal thickness varies greatly from one sample to another, generally it should be kept below ~50 μ or ~20 μm for transmission and reflection measurements, respectively. Sectioning of a sample is usually done at low temperatures (between −10 and −20 °C), that is, by cryotoming. If possible, the sample should be cut without any support. Otherwise, the sample can be imbedded in a medium that maintains the physical integrity of the sample during sectioning. The embedding compound should be carefully chosen to match the hardness of the sample. Furthermore, its IR absorption bands should not overlap with those of interest in the sample, as the embedding compound may penetrate into the sample. In most cases, a liquid hydrocarbon such as paraffin wax is a good choice, as its IR absorption is only seen in the CH region. Penetration of the embedding material into the sample can be avoided in some cases if the embedding compound is placed only at one side of the sample block before sectioning. However, physical integrity of the biological materials may be lost.

Once a thin section is cut, it is placed onto an IR substrate. For transmission microscopy, the substrate should be one of the IR windows described above (see Sect. 3.1). Regular glass windows are only partially transparent in IR region (4000–2500 cm^{-1}) so that only CH stretching region can be probed with a sample on a glass substrate. For reflection microscopy, the media are polished reflective surfaces, like low-e slides.

Biological materials often strongly adhere to IR windows and/or low-e reflective slides, and washing and staining can be done with the sample placed on the substrate. While staining allows better visualization of the sample components, care should be taken as the stains may produce artifacts, either by exhibiting their own spectral features or by changing the IR absorption of the sample by interaction.

5 Band Assignments

Since the IR spectrum is additive (see Sect. 1), most tissue samples can be approximated as a sum of three spectral types, namely, lipids, proteins, and polynucleides. Each of these building blocks contributes to the overall spectrum with its relative concentration. Relevant examples of them are given in Fig. 4.

The spectrum of a protein (Fig. 4a) is characterized by strong amide bands, arising from the protein backbone. Lipids (Fig. 4b) are characterized by strong absorption methyl and methylene bands (CH region around 2900 cm^{-1}). Nucleic acids (Fig. 4c) show strong characteristic absorptions of P=O moieties in 1000–1200 cm^{-1} region, while carbohydrates (Fig. 4d) contain broad O−H stretching bands above 3000 cm^{-1}. For easier viewing, we shall divide the spectrum into several parts and discuss each of them on the basis of the building blocks mentioned.

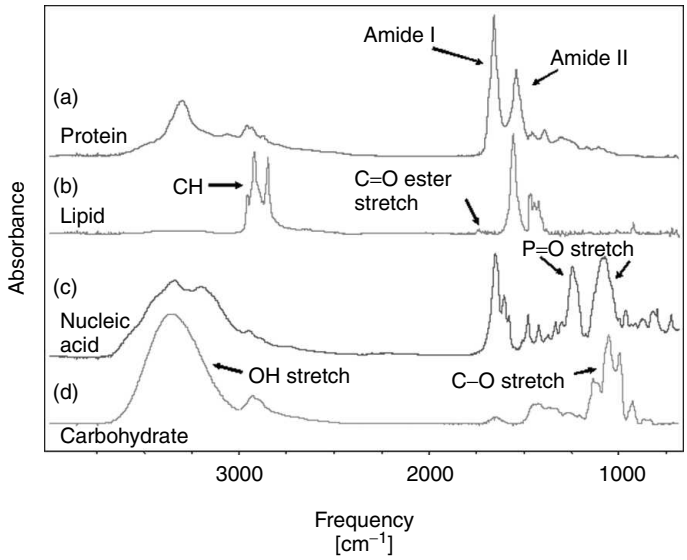

Fig. 4 Fundamental spectral features of biological components.

5.1
Region 3600–3100 cm^{-1}

This region consists largely of O−H and N−H stretching vibrations. Unlike all other bands that are usually sharp with frequencies sensitive to the electron affinities of the groups attached to them, this region is mostly devoid of sharp bands. Instead, a very broad band is observed, due to hydrogen bonding. Its intensity varies with the concentration of the O−H and N−H functional groups. All building blocks show bands in this region, but their shapes and intensities vary. Lipids, having only −OH groups at the end of the molecules, produce only a small hump. Proteins show larger peak due to −NH groups present in every amino acid, while nucleic acids and carbohydrates show distinctive features in this range. Unfortunately, both the intensity and peak position vary significantly with the concentration of water (external or internal) and the interpretation of bands in this region should be taken with caution.

5.2
Region 3100–2800 cm^{-1}

This region of the spectra where −CH stretches are observed is distinctive in lipids. By comparison to alkanes, they are assigned to asymmetric and symmetric CH_3 and CH_2 stretches. Since lipids are long-chain acids, the intensity of the CH_2 absorptions (2920 and 2850 cm^{-1}) is 10 to 20 times that of CH_3 bands (2960 and 2875 cm^{-1}). Proteins show only weak features in this region, as the methyl and methylene groups are present only in the amino acid side chains, with almost equal proportions. Nucleic acids and carbohydrates practically have no CH_3 groups and only weak CH_2 and CH bands are seen in the spectrum.

5.3
Region 2800–1800 cm^{-1}

This region is generally free of bands associated with biological samples, except

for combination bands of water in wet tissues.

5.4 Region 1800–1600 cm^{-1}

The absorption in this spectral region is due mostly to the ester C=O stretching vibrations. Lipids show a distinctive band around 1750 cm^{-1} in this region. Its frequency is strongly affected by hydrogen bonding to water in biological tissues. Nucleic acids show two distinctive features in 1720–1670 cm^{-1}, arising from purine and pyrimidine bases, respectively. Proteins show one major absorption in this region, called *amide I band*, arising predominantly from the C=O group of amide. It is sensitive to the conformation of the protein, as shown below. The frequency of the C=O vibration is sensitive to the hydrogen bonding, and the dielectric constant of the surrounding microenvironment.

The 1700–1610 cm^{-1} amide I envelope consists of several bands, depending on the protein structure. Antiparallel β-sheets (1685–1680 cm^{-1}), turns and coils (1680–1660 cm^{-1}), α-helices (1660–1648 cm^{-1}), unordered structures (1660–1648 cm^{-1}), β-sheets (1640–1625 cm^{-1}), 3_{10} helices (1637 cm^{-1}), and aggregated strands (1625–1610 cm^{-1}) all contribute to this complex region. Fitting of this envelope with series of bands with above frequencies can be used not only to predict protein secondary structure but also to track the conformational changes and assess the kinetics of proteins folding processes.

5.5 Region 1600–1000 cm^{-1}

This region, often-called the fingerprint region, is characterized by a number of different bands. Proteins show two bands (Fig. 4a) in this region. Both bands, usually called amide II and amide III are sensitive to protein conformation, as is amide I. But, because of their complex nature (amide II is predominantly N–H bending coupled with C=N stretching vibration, occurring between 1560 and 1500 cm^{-1}, and amide III involves C–N stretching, N–H bending and CH_2 wagging modes, seen within 1350–1220 cm^{-1}) they are not as useful as amide I in determining structure. Proteins containing acidic amino acid residues (aspartate and glutamate) show COO^- vibrations around 1580 and 1400 cm^{-1}.

Nucleic acids show a series of sharp but weak bands. The most prominent features are the two bands at 1225 and 1090 cm^{-1}, arising from phosphate PO_2^- asymmetric and symmetric vibrations, respectively. Major bands of lipids in this region arise from CH_2 scissoring vibration at 1470 cm^{-1} and C–O–C stretching vibration, around 1060 cm^{-1}. The C–O stretching vibration of carbohydrates occurs at 1200–1000 cm^{-1} and can be strong in liver tissues.

6 Applications: Analysis of Infrared Microscopic Maps and Images

Once the sample is prepared, placed on an IR substrate, and onto the microscope stage, obtaining IR spectral map is rather straightforward. The map is a spatially resolved array of spectra from which a chemical image is generated. The usual scenario is that an area map is set to collect sample scan through an aperture that is the same, or somewhat larger than the wavelength of the lowest frequency band of interest. For instance, if one is interested only in C–H stretching, an aperture of about 4 μm will be appropriate. Larger aperture (~7 μm) settings are needed if the investigator needs to collect amide I band

in addition to the CH stretching, and even larger (12 μm) if the whole mid-infrared spectrum is desired.

When the aperture is set, one chooses the step size, that is, the distance between two adjacent sample points. The step size is usually set to be equal to, or slightly smaller than the aperture size. The latter choice usually produces smoother transition in band intensities of a map. Finally, one chooses a number of scans per data point. For that, the experimenter should do a set of measurements with a different number of scans at the same data point inside the map. Since the counting statistics component (white noise) of the signal-to-noise ratio is proportional to the square root of the number of scans, one chooses the smallest number of scans that produces satisfactory S/N. Although this is very much sample dependent, 32 or 64 scans are usually good choices.

Mapping a sample is done by collecting spectra in either one-dimensional rows, two-dimensional grids, or in a set of predetermined points. In all cases, spectral collections are completely computer-controlled.

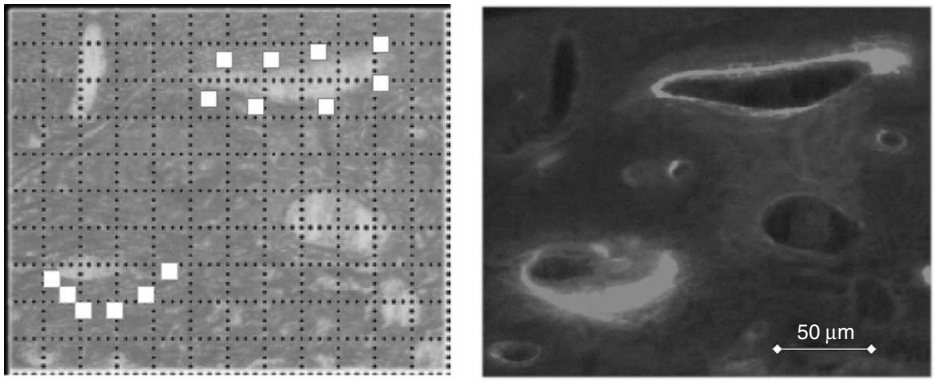
While the interpretation of the data from the map can be done by analyzing a full spectrum of the bands as described earlier for each observed point, this approach is impractical when analyzing a map that may contain hundreds or thousands of spectra. Many FTIR microscopy vendors have developed programs that can present the data in a form of image for easy visualization and comparison to the optical image. Functional group mapping is the most straightforward method, in which a parameter is presented as a function of position in the map. The parameter can be absorption maximum, peak intensity, integrated intensity of a band, or ratios of various parameters. For example, plotting the ratio of band intensity versus that of a baseline produces a reasonable measure of the concentration of a particular species in the map. Each method has advantages and disadvantages. While the intensity of a band (either peak intensity or integrated intensity) is the most straightforward method to obtain the distribution of amount of material represented by a functional group within the map, it may suffer from the baseline fluctuations and changes in thickness of the specimen. Structural properties of a sample can be better visualized by plotting the frequency of absorption maximum as a function of the position in the map, but possible changes in adjacent and/or overlapping bands must be taken into consideration. The ratio of two peak intensities or integrated peak intensities is the method that is often used to avoid the changes of the sample thickness across the area mapped, as well as the synchrotron beam fluctuations over time, but the representing bands must be carefully chosen to avoid problems arising from the baseline changes, artifacts, and so on. Finally, Principle Component Analysis (PCA) is an effective method to display chemical information in a large set of data, as in an IR map, revealing differences between spectra that are not easily seen by inspection and/or spectral subtraction. The major variability between spectra is calculated and concentrated into small sets of values, called *principle components*. Plotting principle components against one another shows clustering of the data.

6.1 Analysis of Bone Chemistry in Osteoporosis

Osteoporosis, characterized by decreased bone density, altered bone architecture,

and increased susceptibility to fracture, is a common and costly disease afflicting millions of women. Although the role of bone density in osteoporosis is well established, little is known about the changes in bone chemistry as the disease progresses. Alterations of several chemical components of bone, including carbonate, phosphate, and collagen, may affect bone strength. Furthermore, in the study of heterogeneous bone tissues, chemical variations at different locations of bone, that is, cortical versus trabecular, may be important in determining the overall mechanical properties of bone.

The application of synchrotron infrared microspectroscopy to examine changes in bone chemistry in a monkey model of osteoporosis has been described. The microscopic matrix and mineral chemistry of osteopenic bone can be monitored by studying the peaks of infrared spectra at amide I (1700–1600 cm^{-1}), carbonate ($\nu_2 CO_3^{2-}$, 825–905 cm^{-1}), and phosphate ($\nu_4 PO_4^{3-}$, 500–650 cm^{-1}). It has been demonstrated that the ratios between the integrated area of phosphate (or carbonate) and amide I bands represent the amount of mineral relative to matrix in bone. Curve fitting the three regions yields information about the compositions of mineral and matrix components that may be altered during disease process. To further analyze these changes, the overall and localized bone quality using two spectral data collection approaches can be used: Mapping broad, randomly selected bone regions to obtain a large number



(a) (b)

Fig. 5 (a) 100× light image from a subchondral region of proximal tibia from one of the ovariectomized animals. The squares within the grid indicate the fields of data collection limited by 20 × 20 μm aperture during mapping. White-colored squares correspond to data collection at the fluorescent labels shown in (b). The aperture size in this case was limited to 20 × 20 μm. For each data point, a spectrum was acquired using 64 coadditions and Happ–Genzel apodization at 4 cm^{-1} resolution. A background spectrum through air (no sample) was collected for absorbance reference. (b) Fluorescent image of the same field. Calcin (green) and alizarin (red) indicate bone formed one and two years, respectively, after ovariectomy. (Reproduced by permission from International Union of Crystallography, from Marinkovic, N.S., Huang, R., Bromberg, P., Sullivan, M., Toomey, J., Miller, L.M., Sperber, E., Moshe, S., Jones, K.W., Chouparova, E., Lappi, S., Franzen, S., Chance, M.R. (2002) Center for Synchrotron Biosciences' U2B Beamline: an internal resource for biological infrared spectroscopy, *J. Synchrotron Radiat.* **9**, 189–197) (see color plate p. xxxiv).

of spectra; and, individual point-and-shoot at regions labeled by fluorochromes to be of a given age, Fig. 5. In both cases, synchrotron light source is necessary for data collection at spatial resolutions near the diffraction limit (3–20 μm). The proximal tibiae of animals at three distinct anatomical regions are of interest: cortical, subchondral, and trabecular bone. A bone density enhancing drug, nandrolone decanoate, was administered to a subset of ovariectomized monkeys as a comparison to the nontreated subjects to demonstrate the effect of the drug on bone chemistry during disease progression.

For visual comparisons between different ratios, contour maps of ratio intensities can be generated using Microcal Origin 5.0 (Northampton, MA) with the same coordinate as in the data collection field. For example, the contour map of carbonate to matrix ratios (Fig. 6) from the same field shown in Fig. 5 demonstrates that areas with low intensities correspond to alizarin labeled region (red label), indicating less carbonate mineralization in the newly formed bone. By comparing the results from diseased monkeys with those from intact as well as treated subjects, we are able to detect specific changes in bone chemistry due to disease and therapy. To date, the results of macroscopic chemical changes examined by infrared mapping has been reported, where a significant decrease in carbonate, and increased acid phosphate content were observed in ovariectomized animals. The microscopic results combining FTIR and fluorescence microscopy further demonstrate localized changes in the amount of

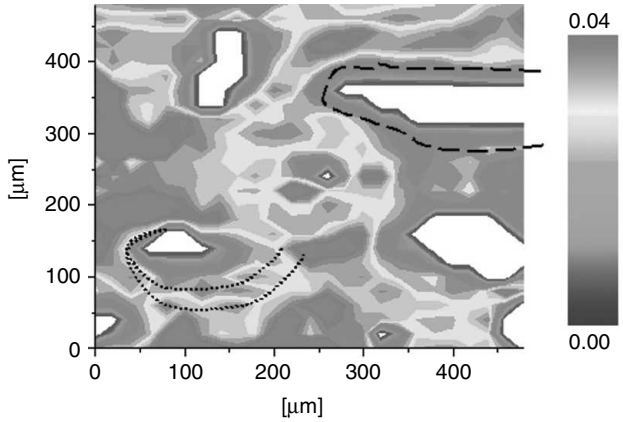


Fig. 6 Contour maps of $\nu_2 CO_3^{2-}$/amide I ratio from the same field shown in Fig. 5. The map was generated by tabulating the ratios obtained from curve-fitting analysis into the same $x - y$ coordinate in Fig. 5(a). The intensity is represented by a color gradient indicated by the column to the right of the figure. (Reproduced by permission from International Union of Crystallography, from Marinkovic, N.S., Huang, R., Bromberg, P., Sullivan, M., Toomey, J., Miller, L.M., Sperber, E., Moshe, S., Jones, K.W., Chouparova, E., Lappi, S., Franzen, S., Chance, M.R. (2002) Center for Synchrotron Biosciences' U2B Beamline: an internal resource for biological infrared spectroscopy, *J. Synchrotron Radiat.* **9**, 189–197) (see color plate p. xxiv).

phosphate and carbonate as well as the degree of collagen crosslinking. These results show that synchrotron FTIR microspectroscopy can study bone tissue chemistry with a level of detail that is not possible with other techniques. In particular, it has the ability to monitor both the mineral and the matrix components of bone simultaneously. In addition, the automated fitting procedures allow the chemical information of the infrared spectra to be rapidly extracted such that quantitative mapping is possible.

6.2 IR Microscopy Studies of Epilepsy and Neurodegeneration in Animals

Hippocampal tissue from humans with chronic temporal lobe epilepsy reveals a specific pattern of neuronal degeneration referred to as *mesial temporal sclerosis*. The predominant feature of this disease includes a selective loss of pyramidal neurons in the hippocampal endblades and frequently in the Sommer sector, that is, CA3 and CA1 areas, respectively. In contrast, pyramidal cells in the transitional zone between the two areas (CA2 area), as well as granular cell layer, subiculum, and fibers *en passage* remain intact. Kainic acid is often used to induce seizures in animals. Neuronal loss is apparent at 24 h, and is maximal at 48 h after the onset of kainic acid status epilepticus. A wide variety of morphological changes associated with dying during development or following a toxic insult is observed in cells. A binary classification scheme suggests that physiologically appropriate death is due to apoptosis and that pathological mechanisms involve necrosis. Necrosis, or accidental or pathological cell death is characterized by rupture of the membrane due to swelling of organelles, so that cytoplasmic contents are released into the extracellular space. In contrast, apoptosis, or physiological cell death is characterized by nuclear condensation and cellular and membrane shrinkage. Apoptosis has been reported to increase following a wide range of pathological states, such as neurodegenerative diseases, adrenalectomy, and seizure.

Visible and infrared images of healthy and diseased neural tissue have been used to observe changes in the pyramidal neurons in the CA3 and CA1 regions. Samples were prepared as follows: An adult rat was exposed to severe status epilepticus and sacrificed by transcardiac perfusion 48 h after the onset of seizure. The normal rat had a sham injection. The brain was fixed overnight in the same perfusate and left in 30% sucrose solution. When the brain sunk, it was rapidly frozen in methylbutane ($-40\,^{\circ}C$) and cut through the dorsal hippocampus in a cryostat ($-18\,^{\circ}C$) into 12-μm thick sections. The tissue was mounted onto BaF_2 windows and placed under the IR microscope. The IR maps of CA1, CA2, and CA3 pyramidal cells and surrounding tissue were collected using 64 scans with 4 cm^{-1} resolution. The aperture size was 10 μm, which is roughly the size of a pyramidal cell (see Fig. 7) and the stage was moved in 10-μm increments. The protein, lipid, disulfide, ketone, and phosphate mid-infrared regions were examined to assess biochemical differences in the tissue samples.

We found that examination of the peak intensities of the amide I band to lipid bands (1654 and 2922 cm^{-1}, respectively) provided an indicator of the disease. As seen in Fig. 7, the IR image of bands closely follows the optical image, indicating that the highest amide to lipid peak

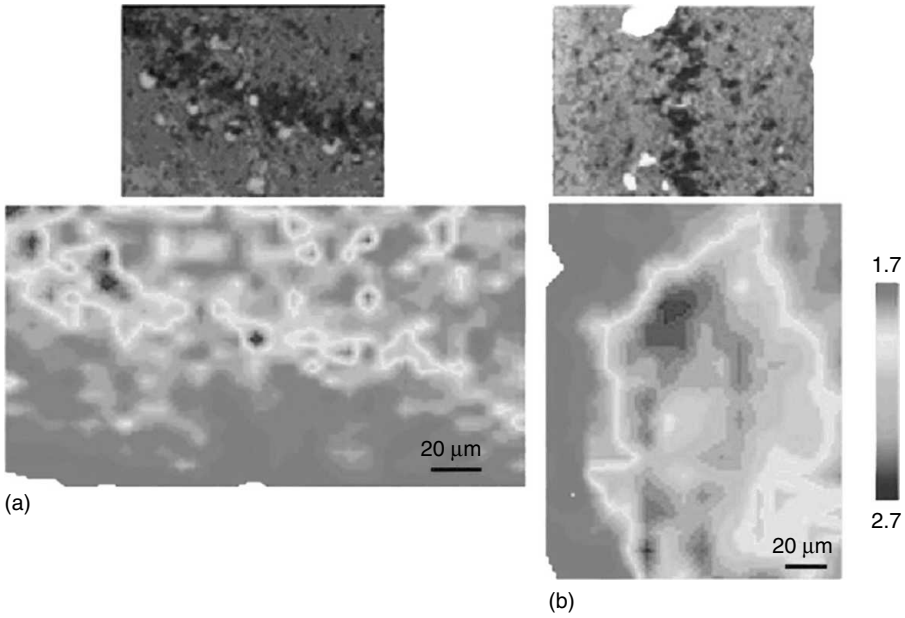

Fig. 7 Optical (top) and false-colored IR images of brain tissue from (a) a normal rat and (b) a rat with severe seizure. Tissues were mounted on BaF_2 windows. The aperture size was 10×10 μm (see the green square at the center of the optical image of normal rat tissue). For each data point in the IR map, a spectrum was acquired using 64 coadditions and Happ–Genzel apodization at 4 cm^{-1} resolution. A background spectrum through a spot without sample was collected for absorbance reference. The map is generated using an amide I to lipid peak height ratio of bands at 1654 and 2922 cm^{-1}, respectively, and the color represents the intensity of the ratio. (Reproduced by permission from International Union of Crystallography, from Marinkovic, N.S., Huang, R., Bromberg, P., Sullivan, M., Toomey, J., Miller, L.M., Sperber, E., Moshe, S., Jones, K.W., Chouparova, E., Lappi, S., Franzen, S., Chance, M.R. (2002) Center for Synchrotron Biosciences' U2B Beamline: an internal resource for biological infrared spectroscopy, *J. Synchrotron Radiat.* **9**, 189–197) (see color plate p. xxxii).

ratio is found within the CA3 cells in the normal tissue. In contrast, the IR image of the tissue sample of diseased animal shows that the amide I to lipid ratio is high not only within the cells, but spreads several tens of micrometers further away from the cell wall. It appears that the diseased neural cells lose their integrity, spreading their biomaterial toward the surrounding tissue. This example indicates the power of IR microspectroscopy to investigate changes in tissues during disease progression.

6.3 Microscopic Structure and Properties of Seeds

Various grain cultures are commonly grown in the world for human and animal diets. High quality grain silage requires attention to details such as plant maturity, speed of harvest, chop length, and silo packing, as they influence the fermentation process, storage losses, palatability, and nutritional value of the resulting feed. The selection of seed varieties has been undertaken throughout the world to

improve the nutritive value and nutrient utilization. To assess total seed chemical composition on protein and carbohydrates, usual procedure involves standard "wet" chemistry, which relies on homogenization of seed and use of harsh chemicals that alter the plant structure and possibly generate artifacts. Probing of the localized chemical microstructures to assess the spatial origin and distribution of components has been conducted by FTIR microspectroscopy, first with a globar source, and later with synchrotron source on varieties of corn, wheat, and barley. Feathers are also considered a potential protein supplement to animal feed as they are widely available as a by-product in poultry and are exceptionally high in protein. A comparison of secondary structure of feather to other protein sources from grain using FTIR microspectroscopy revealed high contribution of β-sheet in feather, up to 88%, whereas α-helix is the main protein component in barley (71%), oat (92%), and wheat (50%) grain. The low α-helix content, as well as other factors including the high keratin content, strong disulfide bonding of amino acids, and the relationship of protein secondary structure of feather to solubility, is believed to be in relationship to the low feather digestibility. Wheat specimen from different wheat cultivars showed that the percentage of α-helix is much higher in hard winter wheats, known for their bread-making quality. The α-helix to β-sheet peak area ratios in hard wheat is between 1.6 and 2.1, while that of soft wheat is about 1.

6.4 Biotransformation of Pollutants in Roots

Root and root exudates were studied by synchrotron FTIR microspectroscopy, in order to obtain information on interaction of plant with the environment. The level of phosphorus in the soil affected lignin concentration in epidermis, and increased level of sugars and lignin precursors in rhizosphere surrounding the root of mung bean. Stem, root, and leaf tissues of a model genetic organism and mutant plants were studied to understand defensive mechanism of the plant toward a predator, Erysiphe spp. fungus.

The plant defense mechanisms toward toxic compounds were the topic of investigation of recent studies. The fate of organic contaminants within the plants used for waste cleanup (phytoremediation), as well as bioavailability of transformed contaminants and their toxicity relative to the parent compound was investigated using benzotriazole as the model compound. This compound is commonly used as a corrosion inhibitor in antifreeze, airplane deicing fluids, gasoline, oil, lubricants, and heat exchanger fluids. The changes in root constituents including carbohydrate, cellulose, lignin, and protein, due to uptake, incorporation, and/or transformation of benzotriazole (BT) were monitored. The distribution of the characteristic CH out-of-plane bending mode of BT at 745 cm^{-1} (Fig. 8) across the IR microscopically scanned region demonstrated a high concentration of BT across the vascular region of BT-treated roots, and a low concentration in the epidermis. This provided evidence that the aromatic ring of BT remained unchanged during the incorporation within sunflower secondary root.

While changes in intensity of the characteristic BT peak were obvious, differences in other portions of spectra are not readily observed (Fig. 9A). This is particularly true for the protein amide I and II regions. To visualize the changes in treated versus untreated sunflower roots better, principal component analysis has been conducted.

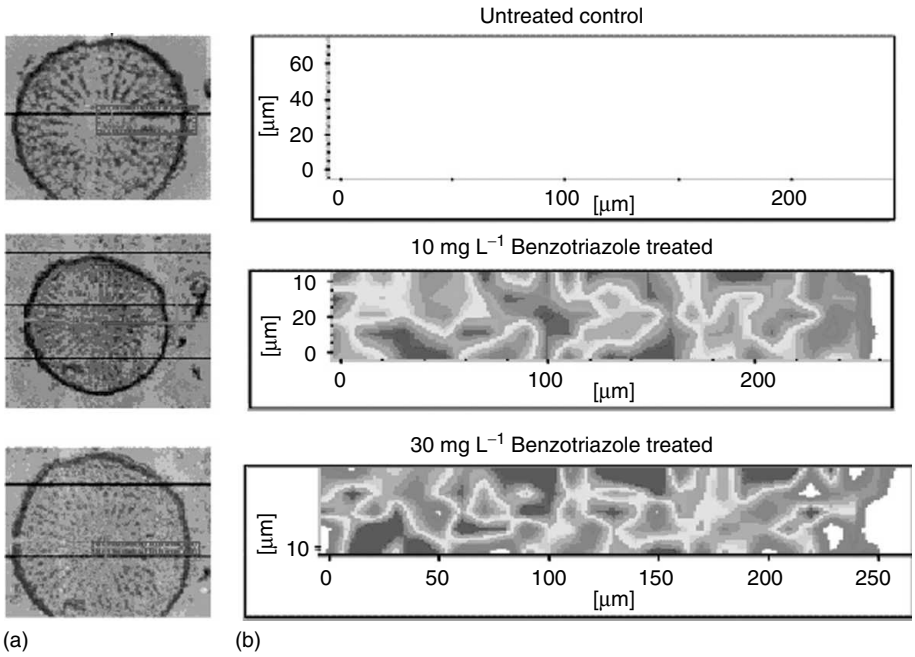

Fig. 8 (a) Visible images of root sections of a control plant and plants treated with 10 and 30 mg L^{-1} benzotriazole. Blue rectangles represent the area mapped by synchrotron IR microspectroscopy. (b) False-color intensity maps of untreated (control) and treated sunflower root sections, processed for the aromatic C−H out-of-plane bending mode of benzotriazole at 745 cm^{-1}. The intensity of the band in the inner (cortex) area of the secondary root is proportional to the initial concentration of the benzotriazole in which the plant was grown. (Reproduced by permission from International Scientific Communication from Marinkovic, N.S., Dokken, K.M., Davis, L.C., Linkovs, D.H., Flinn, J.M., Chance, M.R. (2005) Synchrotron infrared spectroscopy at beamline U2B, *Am. Biotechnology Lab.* **23**, 12–13) (see color plate p. xxxv).

Major spectral variability was observed in 180 data points, chosen from the infrared spectra of each 10 mg L^{-1}, 30 mg L^{-1} BT-treated and untreated roots (Fig. 9B and C). 89% of spectral variability accounted for changes in protein (1650 and 1553 cm^{-1}), benzotriazole peak at 745 cm^{-1}, carbohydrate (1102, 1039 cm^{-1}) and lignin peak (1250 cm^{-1}), revealing that the BT treatment causes damage to the proteins and/or alters their production in the plant tissue, while facilitating production of carbohydrate and possibly altering lignin structure.

6.5 IR Microscopy of Hair Sections

Analysis of human hair is done extensively. In cross-section, human hair is 50 to 100 µm in diameter, and consists of three distinguished regions, that is, the outer region (cuticle), inner region (cortex), and central part (medulla). The cuticle is a 5 µm-thick dense layer that protects the hair fiber. The cortex that is 45 to 90 µm thick determines the strength of the fiber and contains hair pigment (melanin), while loosely packed keratinized cells in 5

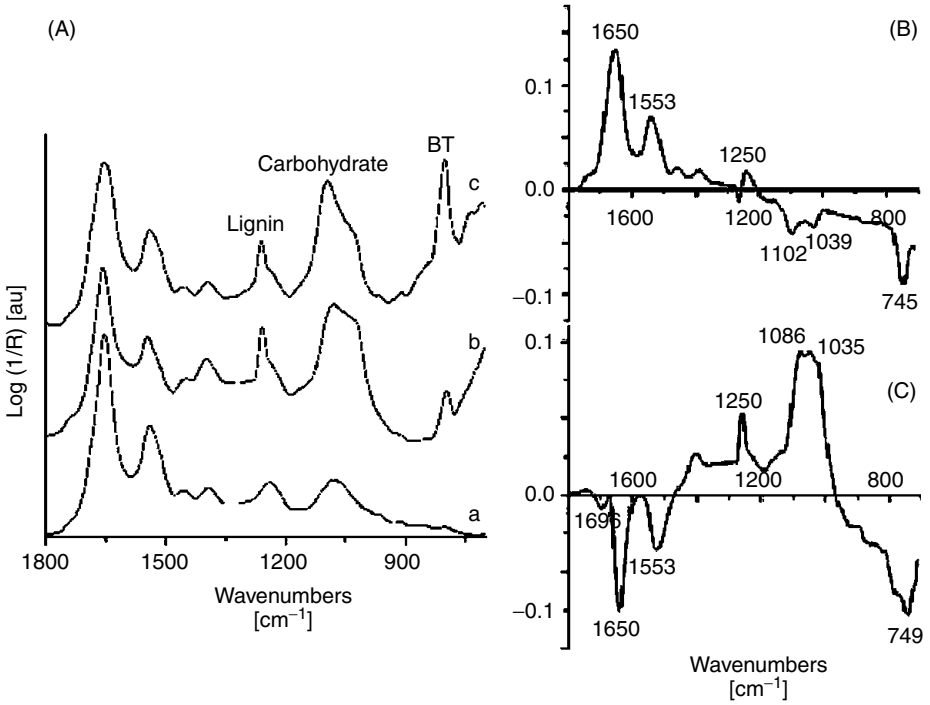

Fig. 9 (A) FTIR spectra of root tips from untreated control, 10 mg L^{-1}, and 30 mg L^{-1} benzotriazole-treated sunflower plants (a, b, and c, respectively). Each spectrum is an average of 10 spectra taken from arbitrarily selected locations from their respective IR maps. The spectra of treated plants roots show the appearance of the characteristic aromatic C—H peak of BT at 750 cm^{-1}, and differences in carbohydrate region at 1000–1100 cm^{-1} and lignin peak at 1250 cm^{-1}, with respect to the control. (B) The first principle component loading shows major variability in the protein amide I and II bands (1650 and 1553 cm^{-1}) and the characteristic BT peak at 745 cm^{-1}. (C) The second PC loading shows major variability in the protein and carbohydrate regions, as well as in lignin and BT peaks.

to 10 μm-thick medulla distributes moisture and nutrients to the hair strand. Even though infrared microspectroscopy of hair is now routinely used in forensic science and was applied for analysis of drug abuse in earlier studies with globar source, only with the high-brightness synchrotron FTIR microspectroscopy was it revealed that drugs are mainly localized in medulla. The latter technique revealed that Caucasian human hair contains fatty acids, mostly present in medulla and to a lesser extent in cuticle, whereas Afro-American hair showed no presence of these long-chain acids, in contrast to previous beliefs. First derivative spectra of hair showed a slight downward frequency shift for the symmetric CH_2 stretch, in agreement with the hypothesis of organized lipids inside the outer layer of hair, such as the skin stratum corneum. Amide I band is different in the three hair parts, suggesting differences in secondary structure composition of the proteins in each region. Chemical images of peptide and lipid bands in transverse hair cross-sections

before and after bleaching showed that keratin, the major protein component in hair containing high concentration of cysteine residues, becomes oxidized after the treatment, producing a sharp sulfonate stretching band around 1040 cm^{-1} in cortex, while medulla stays unaffected.

6.6 Other Biological Applications

Synchrotron IR microspectroscopy was used to show distribution of proteins, lipids, and nucleic acids in a single living cell through 3 × 3-μm aperture, and in a cell undergoing mitosis. Live cyanobacterial cells response to silicification was monitored to understand how microorganisms react to sudden and extreme changes in chemical and physical properties of their environment. Environmentally induced changes in the overall molecular framework of cells were studied during biogeochemical reduction of Cr(VI) on basalt surfaces on a bacterial colony on a magnetite surface during biodegradation of toxic polycyclic aromatic hydrocarbons, and on a micropopulation isolated from a eutrophic lake. Response of a single living human HepG2 cell derived from hepatocellular carcinoma in various concentrations of a model environmental contaminant for the aryl hydrocarbon receptor revealed changes in the phosphate backbone of nucleic acids and intracellular changes due to induction of the *CYP1A1* gene. Human lung fibroblast cells at different points in their life cycle revealed changes in secondary structure of proteins, variation of DNA/RNA content, and packing.

Hypercholesterolomic rabbit liver was probed by functional group mapping and nonsubjective cluster analysis, identifying regions of tissue with similar properties. Human skin on human explants were analyzed to show distribution of lipids inside stratum corneum, epidermis, and dermis, and to assess drug localization. The model drug, 4-cyanophenol with a distinct signature of $\nu_{C\equiv N}$ at 2222 cm^{-1} showed that it penetrates mostly into the stratum corneum, and extends into epidermis, and that the agent does not produce secondary structural modifications of the tissue during penetration.

Synchrotron FTIR spectroscopy was used to characterize organization of proteins in amyloid plaques from individuals with Alzheimer's disease (AD). The affected plaques showed appearance of β-sheet structure at 1630–1634 cm^{-1} inside amide I envelope, while the proteins in surrounding tissue contained mostly α-helical conformation. Classification of the IR spectroscopic data nonsubjectively by multivariate methods showed that IR spectroscopy could potentially be used in the diagnosis of AD from autopsy tissue. Combining two techniques in a single microscope, it was shown that β-amyloid plaques labeled by Thioflavin S could be identified by fluorescence microscopy, and analyzed by synchrotron IR microspectroscopy. Dietary enhancement of iron in drinking water was shown to significantly alter disease progression in the transgenic APP2576 murine model of AD in mice, altering the protein conformation in hippocampal neurons. It is likely that the change of protein secondary structure leads to aggregation of the misfolded protein.

7 Conclusion

Synchrotron infrared microspectroscopy is a powerful method for obtaining

high signal-to-noise spectra at diffraction-limited spot sizes and providing diffraction-limited spatial resolution. The high-brightness advantage of synchrotron source that is typically of 3 orders of magnitude higher than the thermal sources has had a significant impact in biological and biomedical research. In particular, mid-infrared vibrational modes of tissue chemistry can reveal small but significant chemical changes associated with various diseases and altered environmental conditions. The applications of synchrotron IR microspectroscopy are exemplified in neuroscience, bone research, and plant science, showing a variety of possible uses of this rapidly growing technique.

Keywords

Actin
A small protein monomer that concatenates to produce thin filaments when it polymerizes.

Allosteric
Modifications to protein structure occur when the binding of a small molecule or another protein to one site in a protein leads to a conformational change in another part of the protein distant from the site of interaction.

Apoptosis
A process of programmed cell death in which cellular components are dismantled in orderly fashion without leakage of cell contents.

Centromeres
Stretches of DNA sequence generally toward the middle of a chromosome that attract accessory proteins that allow mechanical attachment of microtubules in the mitotic spindle and permit the movement of chromosomes into the daughter cells.

Chaperones
Proteins that bind to other proteins to enable them to fold correctly or to remain soluble.

Chromatin
DNA and its accessory proteins, found *condensed* in chromosomes during mitosis and *uncondensed* in the interphase nucleus, where it is surrounded by a double nuclear membrane.

Cyclic AMP
A messenger molecule within cells that activates a protein kinase (protein kinase A); it is made in a single step from ATP by adenylyl cyclase under the control of transmembrane receptors of hormones or growth factors.

Cytokinesis
The process by which the daughter cells separate following mitosis; it involves the actin-based contraction of a purse stringlike contractile ring that generates the cleavage furrow between the daughter cells.

Depolarization
The usually transient loss of the electrical potential that cells maintain across their plasma membranes by setting up asymmetric ionic concentration gradients; it acts as a signal, above all in nerve and muscle.

Disjunction
The separation of the chromosomes at the start of anaphase in mitosis and meiosis; disjunction allows the chromosomes to be pulled into the daughter cells.

Echinoderms
A phylum that sits at the base of the vertebrate lineage to which sea urchins and sea stars belong.

Enzymes
Proteins that act as catalysts in chemical reactions.

Glycoprotein
Protein that has been modified after translation by the addition of sugars, often branching chains of mannose and glucosamine derivatives.

Histones
Very basic (positively charged) proteins that bind to and order negatively charged DNA.

Homologs
The name given to the complementary chromosome pairs that result from recombination.

Hydrophobic
Molecules prefer nonaqueous environments.

Imprinting
An epigenetic modification of key genes that occurs in placental mammals; it regulates embryonic growth.

Interphase
Comprises all stages of the cell division cycle except mitosis and cytokinesis.

Introns
Stretches of DNA within a gene that do not encode amino acids and are cut out before protein sequence is decoded from messenger RNA.

Kinases
Enzymes that attach phosphate groups to other molecules. Protein kinases turn other proteins on and off in this way.

Lipid bilayers
Separate the cell from the extracellular milieu and also separate the cell's internal compartments; they consist of cylindrical lipid molecules with a long hydrophobic tail and a water-loving head group that assemble into planar sheets, lipid tails inwards.

Microtubules
Long cylindrical tubes that assemble from tubulin protein dimers; the dimers pack in a helical array.

Mitosis
The process that precisely segregates the genes between daughter cells after gene duplication; DNA becomes very tightly coiled and packed into chromosomes that are assembled into a disc and then pulled apart into the daughter cells by microtubules.

NADPH
Nicotine-adenine dinucleotide phosphate in its reduced form; it is used by cells as a cofactor to build molecules as this requires a reducing agent.

Phospholipases
Enzymes that cleave phospholipids and remove some or all of the headgroup.

Polyamines
Large linear molecules with many positively charged amine groups.

Polymorphism
The term given to small sequence differences between the same gene in different individuals within a species; many polymorphisms show no obvious phenotype, while at the other end of the spectrum some polymorphisms give rise to debilitating diseases such as cystic fibrosis and muscular dystrophy; the sum of all polymorphisms account for the genetic differences between individuals.

Proteoglycans
Very large proteins found in the extracellular matrix that have an amino acid backbone and very long carbohydrate side chains.

Proteolysis
The process of protein destruction; all proteins eventually undergo proteolysis, but in some cases, proteins are rapidly destroyed as part of a regulatory mechanism rapidly inactivate their activity; proteins can be cleaved into large fragments by proteases and into very short peptides by a cytoplasmic machine known as the *proteasome*.

S-phase
The phase in the cell division cycle during which DNA synthesis occurs and the genome is duplicated.

Spindle
The mitotic *spindle* is the array of microtubules that attaches to the chromosomes during mitosis and drags the chromosomes into their respective daughter cells; in its shape, this structure resembles spun thread wrapped around its spindle.

Sympatric
Species are found in the same or overlapping geographical areas.

Vesicles
Spherical compartments bounded by a lipid bilayer membrane; their contents are often released into the extracellular milieu; this is achieved by fusion of the limiting bilayer membrane with the plasma membrane.

The key aspect of sexual reproduction is the generation of genetic variation through the swapping of variable lengths of chromosome arms between pairs of homologous chromosomes during meiotic recombination in the germline. Following recombination, it is the general rule that a single (haploid) set of chromosomes is packaged into each male and female gamete (sperm and egg). These two sets of chromosomes, one from each parent, then come together to form a single nucleus: the process of syngamy. This simple outcome is achieved in a complex way through the process of fertilization. Fertilization comprises the delivery of the male set of chromosomes, tightly packaged in a small and motile sperm, to the female set of chromosomes, contained within a much larger nutrient laden and relatively sessile egg or oocyte; at fertilization, fusion of the two gametes occurs as a prelude to syngamy. In addition, fertilization triggers the onset of the very rapid rounds of cell division that quickly produce a very large number of embryonic cells. The cell division cycle must be coordinated with the events of syngamy. Large intracellular calcium signals occur at fertilization and ensure that the events of the cell cycle are controlled to permit successful melding of the parents' genomes.

1
Formation of Gametes

1.1
Meiosis and Genetic Recombination

Each round of sexual reproduction shuffles the genetic pack giving rise to a unique combination of genetic alleles and thus to a unique individual. The shuffling is brought about by recombination, a form of genetic cutting and pasting. Human genetic information is packaged into 22 pairs of fully recombining chromosomes (the autosomes); the X and Y sex chromosomes recombine only in a limited (pseudoautosomal) region and are ignored in this account. Each of the 22 autosomes differs in the genes it carries and in its shape because chromosomes have two arms, each of which varies in length between autosome pairs. The autosome pairs look identical to one another, like twins. But unlike identical (monozygotic) twins, though they carry the same genes, they are not genetically identical: each member of the pair carries different alleles of the same genes. Recombination cuts one or more of the autosome arms in each member of the autosome pair at the same place (in fact almost always at exactly the same nucleotide position in the DNA on the two chromosomes) and then swaps the fragments, pasting them back on the opposite chromosome (Fig. 1a).

Recombination occurs during meiosis, the specialized form of chromosome separation that is believed to have evolved from the more normal mitosis seen each time a somatic cell divides (It has recently been suggested by Krylov, Nasmyth, and Koonin that meiosis may be the phylogenetically primitive form of chromosome separation.). Meiosis is at the center of the mechanism of sexual reproduction and occurs only once as each gamete is formed. A germ cell destined to become a sperm or egg contains 22 autosomes from the father and 22 from the mother (the 22 autosome pairs). Just before meiosis, the germ cell undergoes a round of DNA synthesis. This generates 44 chromosome pairs, consisting of 44 autosomes with the father's alleles (the paternal homologs) and 44 autosomes with the mother's alleles (the maternal homologs). Each homolog pair is joined at the centromere. The outcome of meiosis is a haploid gamete with 22 nonidentical autosomes, so the 88 autosomes at the outset of meiosis must be packaged into four cells. This requires two rounds of cell division (Fig. 1b). The first meiotic division (meiosis I) is very unusual. As a consequence of recombination, pairs of recombined maternal/paternal homologs are formed, attached at the points on the arms at which recombination has occurred (the chiasmata). Chromosomes are pulled apart during meiosis I by microtubule-based forces, just as in mitosis. As the chromosomes line up in the central spindle under the tension generated by the microtubules of the meiotic spindle attached to the centromeres, they are seen to be arranged as pairs of pairs (tetrads). The first pairing reflects the attachments between sister chromatids of both maternal and paternal homologs established during DNA synthesis at the centromere and along the chromosomal arms; the second pairing is due to the chiasmata that are a consequence of recombination. It is a unique feature of meiosis I that when the spindle microtubules pull the chromosomes apart during anaphase, the chromosomes separate at the arms (synaptonemes), not at the centromeres. This results in detachment of homologs at the chiasmata (a process known as resolution) and disjunction of the homolog pairs, leaving the sister chomatid pairs

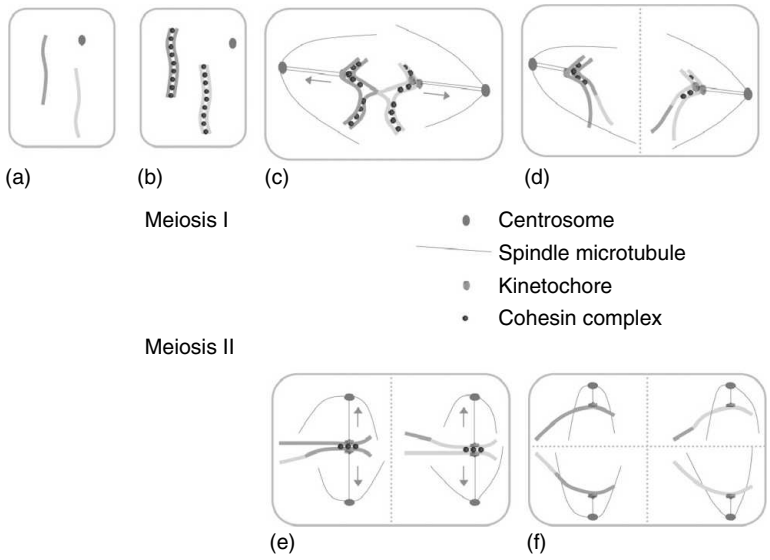

Fig. 1 Recombination and chromatid separation during meiosis. Before meiosis begins, the diploid germ cell contains pairs of homologous chromosomes; for simplicity, only one chromosome pair is illustrated (a). Both chromosomes in each pair undergo DNA synthesis (b); the newly replicated chromosomes are held together along their length by the protein cohesin. Then a complex series of events occurs during recombination that results in the swapping of chromosome arms between the replicated pairs (not shown). The outcome of these recombination events is revealed during the first meiotic division (c): chromosomes aligned on the meiotic spindle can be seen as tetrads, linked by the chiasm that is formed at the site of recombination. At anaphase cohesin falls off the chromosome arms as the chromosomes are pulled toward the centrosomes that organize the meiotic spindle (d); cohesin persists around the kinetochore, maintaining the association between sister chromatids. The meiotic spindle reforms during second meiosis (e). This time cohesin is lost at the kinetochore during anaphase (f). The result is four haploid cells, two of which have swapped chromosome arms in this illustration. With thanks to Neil Hunter for the building blocks of this illustration.

attached at the centrosome. The second meiotic division takes place without any further genome duplication through DNA synthesis. It involves a conventional chromosomal separation at the centromeres, the outcome being four haploid cells.

1.2 Male Gametes

In males, each of the four haploid outcomes of meiosis becomes a gamete. Driven presumably by a strong selection pressure (an unsuccessful gamete has a wasted life and an individual who produces unsuccessful gametes will have no offspring), male gametes have evolved as small, higher energetic cells. As they mature, they lose most of their cytoplasm, develop very highly condensed chromatin due to the replacement of histones with polyamines and grow a very motile tail (flagellum). They also retain a secretory vesicle (the acrosome) whose purpose is

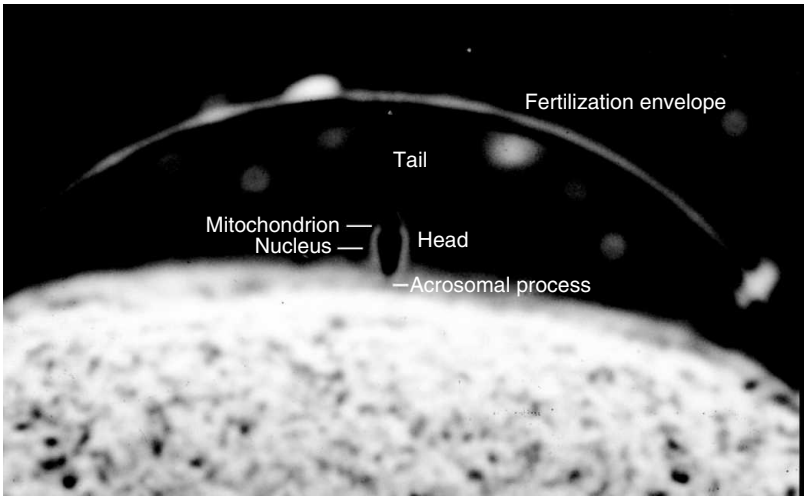

Fig. 2 The spermatozoon as it fertilizes the egg. Light microscope image of a sperm as it fertilizes the sea urchin egg. The sperm has fused with the egg through its acrosomal process and started the calcium wave. The local increase in calcium has caused the local elevation of the fertilization envelope that will exclude other sperm. The sperm head contains the DNA-containing nucleus and the mitochondrion that provides energy to the tail. Once the sperm has fused with the egg, the tail stops beating and stands straight as the sperm enters the egg. The sperm is only 2–3 microns across; the egg is 100 microns in diameter. The disparity in the sizes of the gametes is very obvious in this image.

to secrete digestive enzymes at the time that the sperm is passing through the extracellular matrix surrounding the egg and a mitochondrion or mitochondria to provide the ATP required for motility (Fig. 2).

1.3 Female Gametes

All embryos undergo a period of autonomous development and during this period they require a source of metabolites. As we have seen, sperm offer slim pickings; it is the egg that has specialized to contain a nutrient store (yolk) on which the embryo will live until it can itself feed or undergo uterine implantation. As a consequence, the embryo can grow only a little bigger than the egg itself (by, for example, developing fluid-filled internal cavities). The size of the egg thus determines the size of the autonomous embryo. Chicks undergo autonomous development within an eggshell to a very large size and thus have a very large yolk store. Frog eggs are around 1 mm in diameter and give rise to a macroscopic tadpole. Many eggs, including mammalian eggs are in the 0.1 mm range, with correspondingly smaller microscopic autonomous embryos, but still weigh in at ten times the size and one thousand times the volume of most somatic cells.

Size matters in two ways. First, it sets a constraint when the male and female gametes meet, as the much smaller sperm has had to evolve alongside mechanisms that signal its presence to the relatively enormous egg. We shall return to this.

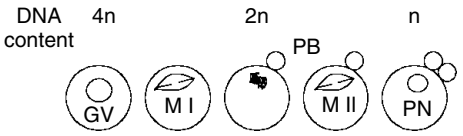

Fig. 3 The female oocyte during meiotic maturation. The immature oocyte is readily identified by its large nucleus (germinal vesicle, GV); by this point, DNA synthesis and recombination have taken place and the oocyte contains four copies of the genome (4n). The first meiotic division (meiosis I, MI) results in the extrusion of a polar body (PB); the oocyte now contains a 2n genomic complement. After second meiosis, a second polar body is formed and the oocyte reforms a haploid (n) pronucleus (PN).

Second, it has made its mark on the way the egg undergoes meiosis.

Strictly speaking, it is an oocyte that undergoes meiosis, the oocyte becoming an egg only once meiosis is complete. In most cases, the oocyte is already a very large cell by the time meiosis occurs, pumped up with yolk by the surrounding nurse cells in the ovary. In the female germline, both meiotic divisions are very asymmetric, both generating a very small cell, budded as it were on the surface of the large oocyte. After meiosis I, the small cell (polar body) contains 46 chromosomes and does not divide further. The polar body extruded during meiosis II contains 23 chromosomes and again has an inconsequential fate (Fig. 3). Thus, of the four possible haploid cells that can be generated by meiosis, only the large oocyte survives in the female germline.

2
Interaction of Sperm and Egg

2.1
Sperm Activation and Chemotaxis

Active sperm have a very limited shelf life. Sperm of external spawners shed into the water column have no ready access to respiratory substrates beyond their own limited stores and sperm of this sort cease to swim within minutes. Mammalian sperm within the uterus are supplied with external substrates; they also have many more mitochondria and can survive as motile and fecund sperm for several days. Mechanisms therefore exist to suppress sperm motility until sperm are delivered to the vicinity of the egg.

A widespread mechanism for suppression of sperm activation appears to be the acidic environment in testis and seminal fluid, combined with a high partial pressure of carbon dioxide. Once the seminal fluid is diluted, pH rapidly increases and activates motility.

Sperm activation may also be mediated or enhanced by signaling molecules released by the egg or present in the uterus. In echinoderm sperm, small peptides released from the egg coat interact with their receptor, a transmembrane guanylate cyclase located in the sperm tail. Stimulation of the receptor increases both pH and calcium concentrations within the sperm, leading to enhanced motility (Fig. 4). Similarly, progesterone stimulates calcium signals in mammalian sperm and enhances motility.

These agents may also be inducing chemotaxis, the directed movement of sperm toward the egg along a chemical gradient, though this is not yet proven. In other animals, for example, ascidians and siphonophores, sperm chemotaxis has been well demonstrated. Chemotaxis between gametes of the fern can be demonstrated using simple kits designed for high school students. It has recently

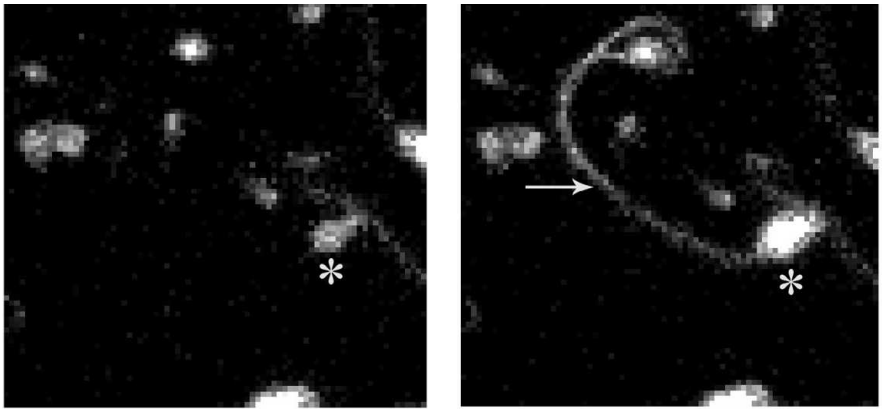

Fig. 4 Calcium signaling and sperm chemotaxis. Calcium ion concentrations can be detected inside cells by using fluorescent dyes whose intensity depends on calcium concentration; sperm head is marked with an asterisk. Sperm have low resting calcium concentrations (left). When the chemotactic peptide speract is added, calcium concentration increases in the tail (arrow); this alters swimming behavior.

been found that human sperm possess receptors equivalent to those found in the olfactory epithelium and that appropriate odorants can induce changes in swimming behavior consistent with chemotaxis.

2.2 The Acrosome Reaction

The naked surface of the egg or oocyte is always well protected, sometimes by thick proteoglycan coats and often in addition with a cloud of accessory cells embedded in this extracellular matrix. Sperm must traverse these barriers in order to reach the plasma membrane and enter the egg and to do so they must dissolve the extracellular matrix. The release of the contents of the acrosomal vesicle is a process akin to the release of neurotransmitters and circulating hormones: a large increase in intracellular calcium concentration triggers fusion of the acrosomal vesicle with the sperm plasma membrane. The acrosomal vesicle contains glycanases and proteases in many cases, capable of hydrolyzing the extracellular matrix.

Fittingly, the release of acrosomal contents is triggered by the proximity of the extracellular coats themselves. In echinoderms, the acrosome reaction can be experimentally triggered by a component of egg jelly in the complete absence of the egg itself. In mammalian sperm, the trigger to the acrosome reaction is a glycoprotein component of the extracellular matrix immediately surrounding the egg, the zona pellucida.

In abalone, the contents of the acrosomal vesicle consist of a protein, lysin, which acts not as an enzyme, but stoichiometrically as a structurally specific chaotropic agent (chaperone) that dissolves the egg vitelline envelope.

One consequence of the acrosome reaction in many species is the formation of the acrosomal process, a fine protrusion at the tip of the sperm head that is the locus of interaction with the egg membrane. This fact is exemplified by the behavior of *Thyone* sperm: they undergo

an acrosome reaction at the very periphery of the egg jelly, sending a 100-µm process through the jelly coat to reach the egg plasma membrane. In *Thyone*, as in other species, the process grows due to actin polymerization. The growing plus end of the actin filaments is at the tip of the acrosomal process while the reservoir of monomeric actin lies at the base of the filament; the rate of growth decreases exponentially, limited by the increasing diffusion time for actin monomers along the length of the growing process. Actin polymerization is triggered by the increase in pH that accompanies the calcium rise that triggers the acrosome reaction.

2.3 Sperm–Egg Interaction and Speciation

Reproductive isolation is the major mechanism driving the formation of new species. This often occurs as a result of geographic isolation of a population, but can also occur sympatrically. Closely related sympatric species may remain speciated by separation of habitat or by asynchronous spawning, but reproductive isolation is very often due to rapid evolution of the molecules that are the gatekeepers for syngamy.

A striking example is the abalone lysin released during the acrosome reaction. There are five species of abalone living sympatrically on the Pacific coast of North America. Their reproductive isolation is due in large part to the species specificity of the lysin reaction: lysins from other related abalone species are much less potent at dissolving the vitelline envelope. Lysins show very little polymorphism within species. Nonconservative substitutions within the protein are very high relative both to housekeeping proteins and to lysin introns, implying very strong positive selection. Lysin interacts with a protein designated VERL in the vitelline envelope. VERL is a very large (>1 m kDa) protein that consists of well conserved ~100 amino acid repeats. Analysis indicates that it is not under strong positive selection. The hypothesis put forward is that VERL undergoes a process of concerted evolution that puts very strong evolutionary pressure on lysin that can lead to speciation. Concerted evolution is a phenomenon found in proteins with multiple repeats. A mutation in one repeat can propagate through all repeats as a result of preferential recombination events. The finding that lysin shows a very low polymorphism within a population indicates that positive selection produced an optimal lysin in response to concerted evolution in VERL that then swept through a population, creating a new species.

Lysin/VERL is the only known example of how sperm/egg receptor interaction may govern speciation. Very little is known about other sperm/egg receptors. It has been suggested that an 18-kDa protein that coats the acrosomal process in abalone (a close relative of lysin, but with little sequence similarity) may be the sperm receptor for the egg plasma membrane. Similarly, the very hydrophobic protein bindin, which coats the echinoderm acrosomal process, may interact with a receptor on the egg plasma membrane. In mammalian eggs, it has been suggested that integrin/disintegrin ligand receptor pairs that are known to be involved in cell–matrix interaction and signaling may be the sperm/egg ligand/receptor at fertilization, but the evidence is contradictory.

2.4 Sperm–Egg Fusion and Sperm Incorporation

Once the sperm and egg plasma membranes are in close proximity, they fuse

to establish continuity of egg and sperm cytoplasm. Cell–cell fusion in general is not well understood and gamete fusion is no exception. The protein bindin that coats the acrosomal process in echinoderms is very hydrophobic, as are the cores of lipid bilayers: it is thought that bindin may promote membrane fusion, not least because it has been found to promote fusion of lipid vesicles *in vitro*. The 18-kDa protein of abalone has been ascribed a similar function. In mammalian fertilization, the integrin/disintegrin interaction may be fusogenic, but there is no sound evidence for this.

It is humbling that we do not yet understand the mechanism of sperm–egg fusion: it represents the moment of fertilization. A variety of observations isolate the event of sperm–egg fusion as the key event at fertilization:

- In echinoderms, sperm–egg fusion causes depolarization of the egg, the first response observed at fertilization that, significantly, much reduces the probability of other sperm fusing with the egg (an electrical block to polyspermy).
- In echinoderms, under certain conditions, sperm–egg fusion is reversible; when it is reversed, eggs may or may not undergo activation and the longer the sperm cytoplasm is in continuity with the egg, the greater the chances of egg activation.
- Sperm–egg fusion is the earliest detectable event at fertilization, as measured by dye transfer between egg and sperm.
- Mammalian sperm carry an enzyme in their cytoplasm that can activate the egg and is delivered to the egg when the sperm fuses with it.

Once the sperm fuses with the egg, it has fulfilled its purpose of finding the egg and fusing with in local competition with tens (mammals) or millions (external spawners) of other sperm. Incorporation

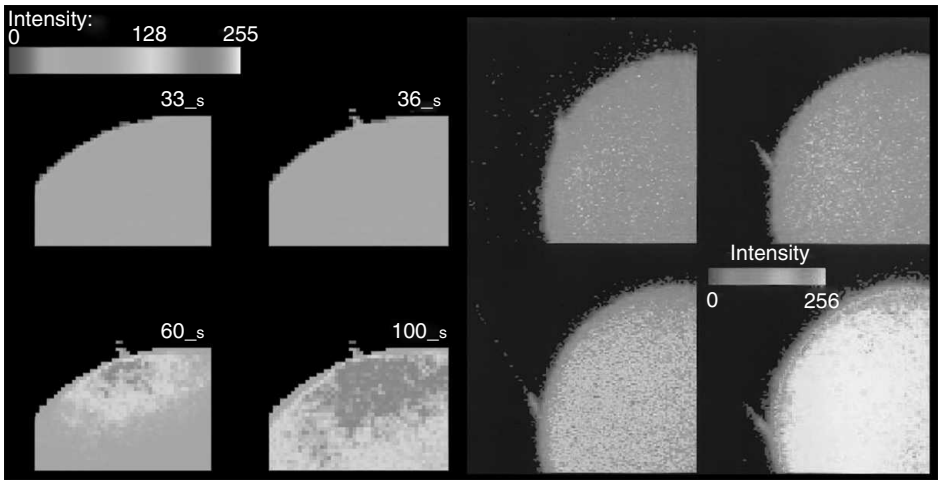

Fig. 5 Sperm–egg fusion in sea urchin and mouse eggs. The eggs contain a fluorescent dye sensitive to calcium concentration. When the sperm fuses with the egg, dye enters the sperm. Sperm–egg fusion triggers an increase of calcium within the egg. The calcium increase occurs many seconds after sperm–egg fusion. Left: sea urchin. Right: mouse.

of the sperm into the egg relies on the egg itself (Fig. 5).

Immediately after sperm–egg fusion, the connection between egg and sperm is tenuous. In many species, fusion occurs at the tip of an acrosomal process little more than 100 nm in diameter. Even during mammalian sperm–egg fusion where it is the side of the sperm head that fuses with the egg plasma membrane, the area of contact is no more than 1 μm^2. Movement of the sperm head (and eventually sperm tail) into the egg is due to actin-based traction. Actin is a force generating protein found in all cells whose acme is rapid and coordinated force generation in skeletal muscle. Actin filaments surround the sperm head, forming an extrusion from the egg surface known as a fertilization cone.

Actin filaments drag the sperm nucleus into the egg. Mitochondria also enter the egg cytoplasm. These degenerate; it is clear by observation and from the genetics of mitochondrial inheritance that all mitochondria in offspring are inherited from the egg and so from the mother. The sperm tail is incorporated. Its components dissolve in the egg cytoplasm, save for the centriole, an organelle that in the sperm organizes the tail microtubules but that, incorporated into the egg, takes over the role of organizing the mitotic spindle microtubules.

Once inside the egg, the behavior of the sperm nucleus depends upon the cell cycle stage of the egg that the sperm has fertilized.

2.5 Syngamy

The blind aim of sexual reproduction is to ensure that one sperm pronucleus coalesces with one female pronucleus. Coalescence of more than the complementary pair of pronuclei leads to genetic chaos. The penetration of more than one sperm nucleus into an egg is known as polyspermy and its consequences are usually fatal to the embryo.

Mechanisms exist to exclude supernumerary sperm. The electrical block to polyspermy (depolarization), found in echinoderms and amphibians, has already been mentioned: the fertilizing sperm depolarizes the egg, making it (for unknown reasons) much harder for subsequently arriving sperm to fuse with the egg. The electrical block is very fast and can come into play within 10 ms of sperm–egg fusion. Other polyspermy blocks are effective, but slower, requiring tens of seconds to take effect. A common mechanism comprises the secretion of the contents of secretory vesicles from the egg after fertilization. In many cases, this leads to the elaboration of a shell (vitelline envelope) around the fertilized egg that sperm cannot penetrate. In mammalian eggs, the secretions lead to inactivation of the glycoprotein that triggers the acrosome reaction in incoming sperm; sperm that have not undergone the acrosome reaction cannot fuse with the egg. In fish eggs, sperm must enter in single file down a narrow canal in the egg investments (the micropyle). Once the egg is activated by the fertilizing sperm, the secretions plug the canal, obstructing the progress of further sperm.

Not all strategies to ensure one-to-one fusion of the sperm and egg nucleus rely on sperm exclusion. Bird eggs are usually polyspermic. Once a lucky sperm nucleus has fused with the egg nucleus, all the other sperm nuclei present in the egg degenerate. In ctenophores, more than luck seems to be in play. The ctenophore egg is naturally polyspermic. The egg nucleus roams from one sperm nucleus

to the next, eventually fusing with one of them; the basis on which this choice is made is unknown.

Once the sperm nucleus has entered the egg it becomes surrounded by a nuclear envelope membrane and is known as the male pronucleus; its counterpart in the egg is the female pronucleus.

As the male pronucleus forms, it swells. The increase in pronuclear volume is due to chromatin decondensation consequent on the replacement of the polyamines surrounding sperm DNA with egg histones.

Ultimately, male and female pronuclei congress and fuse to realize syngamy. Congression of the pronuclei occurs because the male pronucleus is closely associated with the sperm centrosome: it organizes a microtubule array (the aster) that spreads through the egg cytoplasm and captures the female pronucleus, drawing it toward the male pronucleus, while the growing aster pushes against the egg cortex to move both male and female pronucleus toward the center of the egg.

3
Fertilization Calcium Signals

3.1
Calcium Ions are a Universal Egg Activator at Fertilization

In the early part of the twentieth century, Jacques Loeb experimented with various ways of stimulating the egg to undergo development in the absence of sperm – parthenogenesis. Treatment of echinoderm eggs with butyric acid followed by hypertonic seawater was effective, proving Loeb's antivitalist point that life was chemistry but offering no insight into the underlying mechanisms that governed the onset of development.

In the 1970s, a sharp tool became available that enabled these mechanisms to be defined: a calcium ionophore with the designation A23187. Calcium ionophores are small molecules that can carry calcium ions across lipid membranes. It was shown that treatment of unfertilized eggs of both vertebrates and invertebrates with A23187 led to many of the sequelae of fertilization: secretion of cortical secretory granules, DNA synthesis, and migration of the female pronucleus. The eggs had been activated, but did not divide. What was missing? It turned out to be the centrosomes that are required to form the mitotic spindle and that are donated to the egg by the sperm at fertilization. When centrosomes were induced to form in the echinoderm egg using hypertonic seawater, full development ensued in many cases and these parthenotes could be raised to adulthood.

These investigations set calcium ions center stage at fertilization.

3.2
Calcium Signaling

Calcium ions are the bearers of messages delivered by universal signaling systems found in all higher eukaryotes. Calcium ion concentrations are very low in the cytoplasm of all cells and are below micromolar concentrations at rest. It is postulated that calcium ion concentrations must of necessity be very low in the cytoplasm because of the existence of high concentrations of inorganic phosphate, itself a key component of intermediary metabolism. High concentrations of calcium and phosphate cannot coexist because of the low solubility product of calcium phosphate salt. On the other hand, calcium concentrations are in the millimolar range in the seas and in the body fluids of metazoans,

leading to very large gradients of calcium concentration across cell membranes. The existence of these gradients has two consequences. One is that calcium ion pumps driven by the cell's metabolism must constantly eject calcium from the cell since no lipid membrane is completely impermeant to calcium. The second is that relatively small calcium fluxes across the plasma membrane can give rise to large and rapid changes in the intracellular calcium concentrations. The latter consequence makes the cytoplasmic calcium concentration very suitable as an energy-efficient cell signal.

Calcium fluxes across plasma membranes control neurotransmitter release and are the basis of all neuronal activity. In skeletal muscle, calcium causes contraction but is released into the cytoplasm not from the extracellular fluid but from a pervasive network of reticular internal membranes that form a compartment known as the sarcoplasmic reticulum. This arrangement allows calcium ion concentrations to increase rapidly throughout the cytoplasm without the diffusion delays that arise when calcium enters through the plasma membrane. The reticular network is present in other cell types, where it is known as endoplasmic reticulum (ER). It exists not solely as a source of calcium signals; in fact, its primary purpose is to permit the folding and export of proteins destined for the plasma membrane either as integral membrane proteins or as secreted products. The concentration of calcium ions in ER is closer to the concentrations in extracellular fluid than to that of the cytoplasm and is maintained by a calcium pump. We know that folding and export of ER proteins is compromised when the calcium concentration in the ER falls, so it is reasonable to suppose that the compartment's high calcium concentration exists to provide an environment for proteins comparable to that they will experience once they leave the cell. But, as with the plasma membrane calcium gradient, the ER calcium gradient has been exploited in evolution as a calcium signaling system.

3.3 Fertilization Calcium Waves

When the calcium ionophore is used to activate an unfertilized egg, it is causing the release of calcium from the internal calcium stores of the ER. This is easily demonstrated by removal of all calcium external to the egg: this has no effect on egg activation. It is also possible, though rather more complicated, to demonstrate that calcium ion concentrations increase at fertilization.

The first demonstrations of fertilization calcium increases employed a protein (aequorin) that emits light in response to calcium in a graded way. The increase in calcium at fertilization could be seen as a ring of light travelling through the peripheral cytoplasm of a large medaka fish egg. This established the basic features of the fertilization calcium signal as a large increase in cytoplasmic calcium that arises at the point of sperm–egg fusion and traverses the egg as a constant velocity reaction-diffusion wave. Similar waves were observed in frog, echinoderm, nematode, and mammalian eggs using both aequorin and more convenient fluorescent calcium indicators developed by Dr Roger Tsien (Fig. 6).

Fertilization calcium waves are the largest and longest calcium signals measured. They rise to around 5–10 μM and last for many minutes. Preparation for these large explosive signals takes place

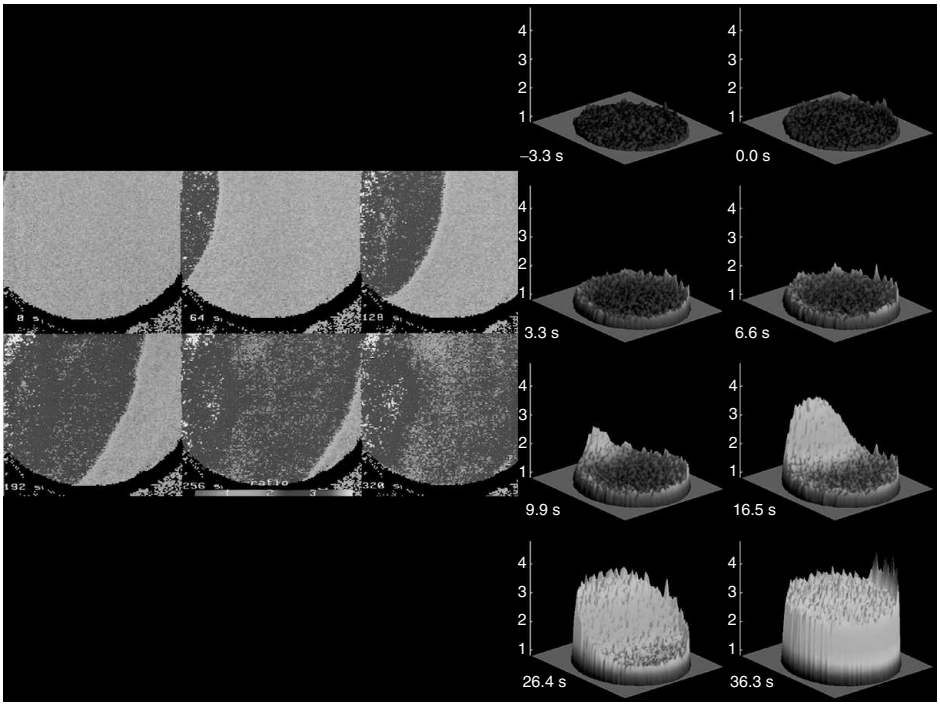

Fig. 6 Fertilization calcium waves in sea urchin and frog eggs. Calcium sensitive dyes are used to detect calcium waves. Warm colors reflect high calcium concentrations. The calcium wave crosses the sea urchin egg in around 15 s with a velocity of around 5 μm s^{-1}. The wave has a similar velocity in the frog egg, but here it takes 5 min to traverse the egg as it is over 1 mm in diameter. Left: frog egg. Right: sea urchin egg. A small early increase in calcium concentration can be seen at the egg periphery, a consequence of a calcium action potential that is triggered by sperm–egg fusion.

during meiosis. As meiosis progresses, the oocyte becomes competent to generate a large calcium wave; after fertilization, this competence disappears. The calcium ionophore experiments tell us that the waves' purpose is to initiate development and it is reasonable to suppose that their extent, magnitude, and duration are necessary to ensure that each part of the egg cytoplasm receives the message that fertilization has occurred. They ensure that the small and local interaction that occurs between egg and sperm is amplified and transmitted throughout the egg.

3.4 Repetitive Fertilization Calcium Transients

Both ascidian and mammalian oocytes manifest multiple large calcium transients at fertilization. In ascidian oocytes, the locus of initiation of the calcium wave migrates with the male pronucleus as it moves toward the oocyte's vegetal pole. In mammalian oocytes, the first few calcium transients originate at the point of sperm – egg fusion, but thereafter, each calcium transient appears to rise homogeneously within the oocyte cytoplasm. This behavior can be explained by proposing

that each transient is generated by a factor associated with the sperm and male pronucleus. In ascidian oocytes, it is supposed that this factor remains closely associated with the male pronucleus, while in mammalian oocytes, the factor slowly diffuses away from the male pronucleus to become uniformly distributed in the cytoplasm. We shall consider the likely purpose of the repetitive transients when we come to discuss the link between fertilization and the cell division cycle.

3.5 Signal Transduction during the Fertilization Calcium Wave

The question before us is how sperm–egg fusion, an event that initially involves a cytoplasmic bridge as little as 100 nm wide, is able to trigger the large fertilization calcium wave. An analogy is that the fertilization calcium wave is an explosion and that the sperm lights a fuse to set it off. This leads to two further questions: what gives the calcium wave its explosive properties and how is the fuse lit? We shall answer them in turn.

3.5.1 Reaction Diffusion Waves

Explosions occur because the products of a chemical reaction further increase the rate of the reaction itself in a process of positive feedback. The fuel for the calcium explosion at fertilization is the calcium stored within the ER. Positive feedback occurs because of the particular properties of calcium channels that exist in the ER membrane: the probability of their opening increases when cytoplasmic calcium increases. Once calcium rises at a point within the cytoplasm, a wave of calcium release will propagate from that point (Fig. 7). There is good evidence for this mechanism in heart cells made to propagate artificial calcium waves.

The identity of the calcium channel in the ER responsible for the fertilization calcium wave was determined by

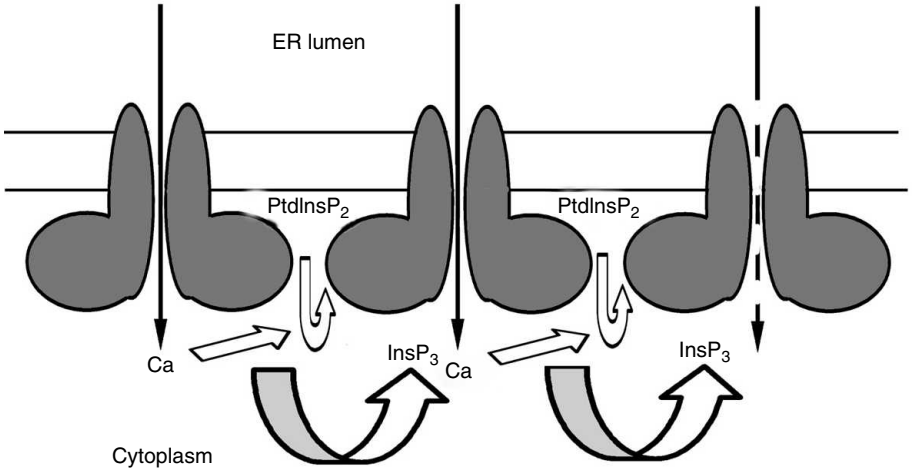

Fig. 7 Mechanism of propagation of the fertilization calcium wave. The calcium wave propagates via calcium-dependent production of $InsP_3$ and diffusion of calcium from one release channel to the next. Both $InsP_3$ and calcium are required in the vicinity of the channel to trigger channel opening and movement of calcium from the ER into the cytoplasm.

investigation of the phosphoinositide messenger pathway, a ubiquitous signaling pathway in cells of higher eukaryotes. The substrate of this pathway is phosphatidylinositol bisphosphate ($PtdInsP_2$). A signaling event, for example, the binding of a hormone or neurotransmitter to its receptor, leads to activation of a specific phospholipase C that hydrolyzes $PtdInsP_2$ to produce two products, inositol trisphosphate ($InsP_3$) and diacylglycerol. $InsP_3$ is a small sugar that causes calcium release from ER. It achieves this by binding to and allosterically activating an ER calcium channel known as the $InsP_3$ receptor ($InsP_3R$), causing it to open. Calcium in the cytoplasm is a coactivator of the $InsP_3R$. The sequence in which $InsP_3$ and calcium are presented to the channel is crucial: if calcium binds after $InsP_3$, then the channel is activated, but if it binds before, $InsP_3$ is unable to open the channel.

Calcium waves can be triggered in eggs by injecting very small amounts of $InsP_3$ into unfertilized eggs and can be blocked by agents that prevent $InsP_3$ from interacting fruitfully with the $InsP_3R$. These observations demonstrate that the $InsP_3R$ is the calcium channel responsible for propagation of the fertilization calcium wave, but they also suggest that the mechanism by which the wave propagates is more complex than that established for calcium waves in heart cells.

The properties of the $InsP_3R$ are not immediately consistent with the observation that very small quantities of $InsP_3$ are sufficient to trigger a calcium wave since once the locally injected $InsP_3$ is diluted by diffusion into the large volume of the egg, its concentration is insufficient to activate the $InsP_3R$ which, as we have seen, requires coactivation by both $InsP_3$ and calcium. There is evidence, in fact, that increases in calcium induce further hydrolysis of $PtdInsP_2$, generating $InsP_3$ locally as the wave propagates. The mechanism of wave propagation thus relies on two intertwined positive feedback pathways, calcium-induced production of $InsP_3$ and coactivation of the $InsP_3R$ by $InsP_3$ and calcium (Fig. 7).

3.5.2 Initiation of the Calcium Wave by the Sperm

The simplest idea is that the sperm generates a small amount of $InsP_3$, so setting off the calcium wave in much the same way as happens when $InsP_3$ is microinjected. This is almost certainly the case, though there is no direct evidence for an increase in $InsP_3$ in the tiny volume close to the point of sperm–egg fusion.

The evidence that an increase in $InsP_3$ triggers the fertilization calcium wave is more subtle. A significant amount of time elapses after sperm–egg fusion before the increase in cytoplasmic calcium that marks the onset of the wave is seen. In echinoderms, around 10–20 s elapses, comparable to the time it then takes for the wave to cross the egg; in mammalian eggs, several minutes pass. What is found is that an agent that interferes with the activation of the $InsP_3R$ increases this latency.

$InsP_3$ is generated by activation of $PtdInsP_2$-specific phospholipases. There has been a debate about which of these phospholipases is responsible for triggering the calcium wave. It was initially thought that an interaction of the sperm with an egg receptor might activate the β-form of phospholipase C (PLCβ); PLCβ is known to be coupled to transmembrane receptors in all cell types examined. However, as it became clearer that sperm–egg fusion was the key activating event at fertilization, attention shifted to another form of phospholipase, PLCγ, that is activated

by phosphorylation on tyrosine. Protein fragments that were able to compete with and block either PLCγ or tyrosine (Src family) kinases were found to increase the latency of the fertilization response and at higher concentrations, to block it completely. Mammalian eggs were, however, an exception, being completely insensitive to these inhibitors. On the assumption that the activating phospholipase would be present in sperm, the mammalian testis was screened for the existence of appropriate phospholipases. A novel phospholipase found only in testis (PLCζ) was shown to induce repetitive calcium transients when expressed in unfertilized mouse eggs.

The picture we have of signal transduction at fertilization is that a protein (Src kinase, PLCγ, PLCζ, depending on species) passes into the egg when sperm and egg fuse. The presence of this protein in the egg leads to the very local production of $InsP_3$. As the latent period progresses, a concentration of $InsP_3$ builds up sufficiently to trigger the onset of the explosive fertilization calcium wave (Fig. 7). Observation of the repetitive fertilization calcium transients in ascidians and mammals suggests that in these species, the activating protein is bound to a component of the sperm head. In ascidian oocytes, the association persists as the male pronucleus forms, while in mammalian eggs, the protein (PLCζ) is thought to dissociate from the male pronucleus (see Sects. 3.4 and 4.3.1).

4
Fertilization and the Cell Division Cycle

4.1
Fertilization Occurs at Different Stages of the Cell Division Cycle in Different Species

It is striking given the ubiquity of calcium signals at fertilization that there are significant differences between eggs of different species in the cell cycle stage in meiosis at which fertilization occurs. Meiosis comprises two cell divisions without an intervening S-phase. Fertilization can occur before the first meiotic division begins, at metaphase of first meiosis, at metaphase of second meiosis, and in interphase once meiosis is complete (Fig. 8). With very few exceptions, this is because at the time that the egg is most receptive to sperm, its cell cycle has arrested at one of the above stages, a stage specific to the species in question.

4.2
Maturation Promoting Factor Plays a Part in Meiosis and in Meiotic Arrest

Classic experiments in the field of cell cycle control showed that cytoplasm from oocytes arrested and awaiting fertilization in meiosis I or meiosis II would induce the maturation of immature oocytes. Similarly, classical experiments in the genetics of yeast cell cycle control genes determined that two key components of

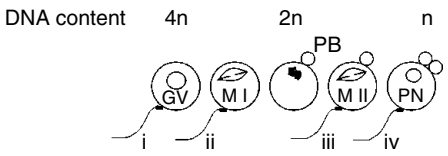

Fig. 8 Cell cycle arrest before fertilization. Oocyte of different species arrest before fertilization at different points of the meiotic division cycle. Some are fertilized as immature oocytes (i: clam), some during first meiotic metaphase (ii: other molluscs, ascidian), some during second meiotic metaphase (iii: frog, starfish, mammals) and some after meiosis at the start of the first mitotic cell division cycle (iv: sea urchin).

maturation promoting factor activity were cdk1, a protein kinase, and its activating partner, cyclin B.

Cdk1/cyclin B activation linked to accumulation of cyclin B drives the cell into meiosis or mitosis, causing condensation of chromatin and formation of the mitotic or meiotic spindle. Oocytes (and other cells) arrested at metaphase show high levels of cdk1/cyclin B activity, but what marks them out is the persistence of this normally transient activity: the persistence leads to cell cycle arrest.

Stabilization of cdk1/cyclin B activity during metaphase cell cycle arrest is due to what appear to be the two other components of maturation promoting factor, a protein termed mos and its target, MAP kinase. Mos is a protein unique to meiotic maturation. Its transcription early during maturation leads to increasing levels of MAP kinase activity. MAP kinase activity remains high throughout meiosis until fertilization occurs. It is responsible for the persistence of cdk1/cyclin B activity (Fig. 9) and, incidentally, for the suppression of S-phase between meiosis I and meiosis II.

Persistent activation of cdk1/cyclin B accounts for the two metaphase cell cycle arrest points during meiosis observed in various species, but other explanations are necessary to explain cell cycle arrest before meiosis begins or after it is completed.

Cell cycle arrest before the onset of meiosis is seen in most organisms. In most species, premeiotic arrest is a distinct stage preceding the prefertilization arrest that occurs later in meiosis and that has already been discussed earlier. Ovaries contain many immature oocytes, a proportion of which are recruited by hormonal stimulation to begin maturation. It is thought that hormonal stimulation leads to a fall in the second messenger cyclic adenosine monophosphate (cAMP). In species whose oocytes are fertilized when immature, it is the fertilization calcium signal that triggers the onset of maturation and reinitiation of meiosis (In some molluscs fertilized at this stage, calcium influx across the plasma membrane takes the place of a calcium wave.).

Cell cycle arrest in interphase of the first mitotic cell cycle occurs in some echinoderms. This arrest can be explained by the suppression of protein synthesis by a relatively acidic cytoplasmic pH and the maintenance of a redox state that lead to low levels of the synthetic nicotine-adenine dinucleotide phosphate (NADPH).

4.3 Calcium Signals and Cell Cycle Progression at Fertilization

4.3.1 Metaphase Arrest

Persistent cdk1/cyclin B activity driven by mos/MAP kinase is the cause of the cell cycle arrest at metaphase in oocytes. Inactivation of these kinases by removal of both cyclin B and mos is how the

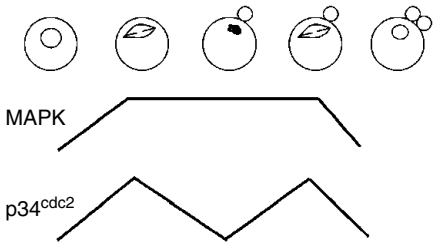

Fig. 9 MAP kinase and cdk1 during meiotic maturation. MAP kinase activity remains high throughout meiosis, while cdk1 activity dips between meiosis I and meiosis II.

fertilization calcium signal causes meiosis to resume.

Frog oocytes are arrested during meiosis II. The fertilization calcium wave triggers cyclin proteolysis by the proteasome through activating calmodulin and so calmodulin-dependent protein kinase II (CamKII). CamKII in turn activates another molecular machine known as the *anaphase promoting complex* (APC) that targets cyclin for destruction by the proteasome. A parallel mechanism, activation of the calcium-dependent protease calpain, leads to proteolysis of mos. In frog oocytes, the proximal cause of anaphase onset is the destruction of cyclin; destruction of mos occurs later than cyclin destruction. Mouse oocytes are also arrested at meiosis II awaiting fertilization. In mammals, 10 to 12 h elapses between fertilization and formation of the nuclear membrane around male and female pronuclei, the lengthy period coinciding with the process of imprinting, found only in mammals. During this period, calcium transients occur every few minutes and cyclin B is slowly degraded, the rate extent of cyclin degradation determined by the frequency of calcium signals. Formation of the pronuclear membranes marks the end of meiosis and coincides with the final disappearance of cyclin B. Mos, on the other hand, is degraded within a few hours. Ascidian oocytes are arrested before fertilization at metaphase of meiosis I. A first set of calcium transients occurs immediately after fertilization, leading to degradation of cyclin B and exit from meiosis I. Mos/MAP kinase activity is not affected by this first set of transients (remember that a role of mos/MAP kinase is to suppress S-phase in the interval between the two meiotic divisions). The repetitive transients begin again as the oocyte enters meiosis II, again leading to degradation of cyclin B and, on this occasion, degradation of mos too. The events described in this paragraph are summarized in Fig. 10.

The reader will have noted a correlation between the state of the nucleus and the occurrence of repetitive calcium transients: the transients are present during meiotic divisions when chromatin is condensed and the nuclear envelope is absent, and are absent during interphase when chromatin in decondensed and a nuclear envelope surrounds the membrane. The transients may indeed be triggered by a factor that is sequestered in the nucleus and released when the nuclear envelope breaks down as the oocyte enters meiotic division. The evidence for this is that nuclei isolated from first cell cycle interphase in mouse embryos will break down under the influence of cdk1/cyclin B when transferred to unfertilized mouse oocytes and induce repetitive calcium transients. The simplest explanation is that PLCζ, the egg activator from the sperm, is sequestered into the nucleus as the nuclear envelope reforms. This conjecture is consistent with observations that repetitive calcium transients continue indefinitely when import of proteins into the nucleus though the nuclear pores are blocked.

4.3.2 Interphase Arrest

Little more is known about how calcium lifts the cell cycle blockade after fertilization of immature oocytes than that calcium signals are known to be capable of antagonizing signaling by cyclic AMP.

Sea urchin eggs are arrested after completion of meiosis, in interphase of the first cell cycle. The fertilization calcium wave stimulates a calcium-dependent NAD^+ kinase to generate NADP, which is rapidly reduced in the cell to NADPH, providing fuel for protein synthesis. Activation of phospholipase C is known to generate

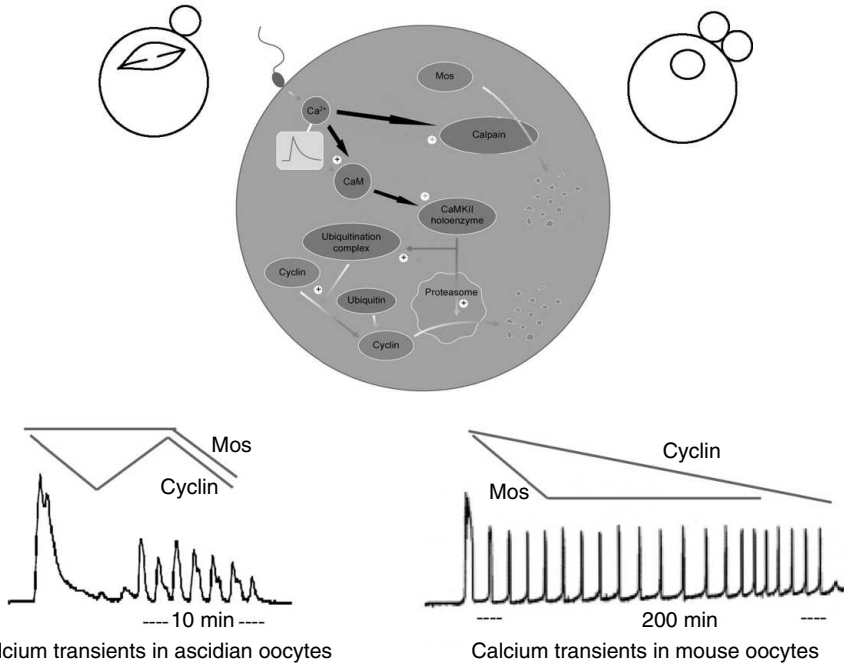

Fig. 10 Destruction of mos and cyclin B at fertilization. Two calcium-dependent pathways for proteolysis at fertilization. One degrades mos by activating calpain. The other activates CaMKinase II to stimulate the APC and cyclin degradation by the proteasome. Calcium dependent proteolysis is rapid in ascidians; in mouse and other mammals mos is rapidly degraded, but cyclin degradation takes several hours.

a diacylglycerol from $PtdInsP_2$ in addition to $InsP_3$ (Fig. 7). At fertilization in the sea urchin egg, the diacylglycerol so generated activates a protein kinase C (no relation of phospholipase C) in the egg plasma membrane in turn stimulating a sodium–hydrogen antiporter that ejects hydrogen ions from the egg, returning the cytoplasm to its normal pH of 7.2. The suppression of the protein synthetic machinery is lifted, cyclin synthesis begins, and the cell cycle proceeds.

4.4 The Cell Cycle and Syngamy

The behavior of the male pronucleus once inside the oocyte or egg after fertilization depends on the point at which fertilization occurs: during or after meiosis. Oocytes fertilized during meiosis must complete meiosis to generate a haploid female pronucleus with which the male pronucleus can undergo syngamy. In this case, the male pronucleus remains separate with its chromatin in a condensed state. Once meiosis II is completed, cyclin B/cdk1 activity falls and the male pronucleus develops a nuclear envelope, as does the female pronucleus. Syngamy comprises the mixing of male and female genomes and occurs through fusion of the pronuclei's nuclear envelopes. S-phase of the first mitotic cell cycle often begins before syngamy. In an extreme case, in mouse

zygotes, S-phase is completed and the nuclear envelope breaks down as the zygote enters the first mitotic division before syngamy occurs. Syngamy occurs on the metaphase plate as male and female chromosomes are captured by spindle microtubules.

5
Calcium and Cell Cycle Control

5.1
Cell Cycle Checkpoints

It is noteworthy that the same cytoplasmic calcium signal, the wave generated by the sperm, operates to trigger resumption of the cell cycle at three distinct points in the cell cycle in different organisms: G2/M, metaphase of MI and MII (which are formally equivalent) and G1. The question arises as to whether these fertilization mechanisms are specific examples of a more general requirement for calcium during cell cycle progression of all cell types.

More general study of the regulation of the cell cycle in yeast and in mammalian somatic cells as well as in embryos has led to the concept of cell cycle checkpoints. The concept is straightforward: before a cell makes a crucial step through the cell cycle, a checkpoint mechanism is invoked that is designed to ensure that everything is correctly in place, a preflight checklist as it were. Two examples of this are the DNA damage checkpoint and the mitosis exit checkpoint.

DNA replication is not a faultless process. Errors are introduced during copying of the DNA strands that are then repaired during late S-phase. The point here is that if mitosis were to occur before repair had taken place, then one or both daughter cells would inherit mutations that resulted from errors introduced at S-phase. The DNA damage checkpoint mechanism is invoked by damaged DNA; while it is active, the cell cannot proceed into mitosis.

The mitosis exit checkpoint is invoked during mitosis to ensure that all chromosome pairs are captured and properly aligned on the metaphase plate before they are separated by the processes of anaphase. A single misaligned chromosome will prevent mitosis. The checkpoint machinery monitors attachment of two sets of microtubules to the chromosome and also verifies by measuring tension in the microtubules that they are correctly attached to the spindle poles. In this instance, the checkpoint mechanism aims to avoid an unequal distribution of chromosomes into the daughter cells. This condition known as *aneuploidy* leads to cell death or on occasion to uncontrolled cell proliferation. A third checkpoint exists at the beginning of the cell cycle in G1. Here, a cell decides, on the basis of signals from its environment, whether it will differentiate, commit suicide (apoptosis), or progress into the cell cycle and divide. The cell cycle stage at which oocytes are found to arrest in the cell cycle correspond to the stages at which these checkpoints act.

Oocytes arrested in G2 are stopped at the stage at which the DNA damage checkpoint acts, those arrested at metaphase are stopped at the mitosis exit checkpoint stage, and those arrested in G1 resemble those cells making choices about whether to divide, die, or differentiate. It is thus very likely that cell cycle arrest before fertilization makes use of underlying cell cycle checkpoint mechanisms.

5.2 The DNA Damage Checkpoint

The DNA damage checkpoint operates by preventing activation of the mitotic kinase cdk1/cyclin B. It does this by preventing a phosphatase (cdc25) from removing a phosphate group on cdk1 that inhibits kinase function. It has been shown in mouse oocytes that activation of cdc25 is necessary and sufficient to bypass the G2/M block and trigger resumption of meiosis. In most oocytes, as mentioned earlier, resumption of meiosis is triggered by a fall in cyclic AMP (Fig. 11). In mouse oocytes, it has been shown that cdc25 is downstream of the reduction in cyclic AMP levels. The calcium transient in oocytes fertilized at G2/M may activate cdc25 via calmodulin-dependent protein kinase II, as it has been shown that progression through the G2/M checkpoint in mammalian somatic cells involves activation of this kinase.

5.3 The Mitosis Exit Checkpoint

The mitosis exit checkpoint operates by preventing activation of the APC that targets key proteins for destruction including securin and cyclin B. Loss of securin leads to loss of adhesion between paired chromosomes on the metaphase plate, allowing them to separate and spring to the poles; loss of cyclin B leads to inactivation of the cdk1/cyclin B kinase, permitting decondensation of chromatin and reformation of the nuclear envelope. These events are triggered by the fertilization calcium transient in oocytes arrested at metaphase meiosis I and meiosis II before fertilization.

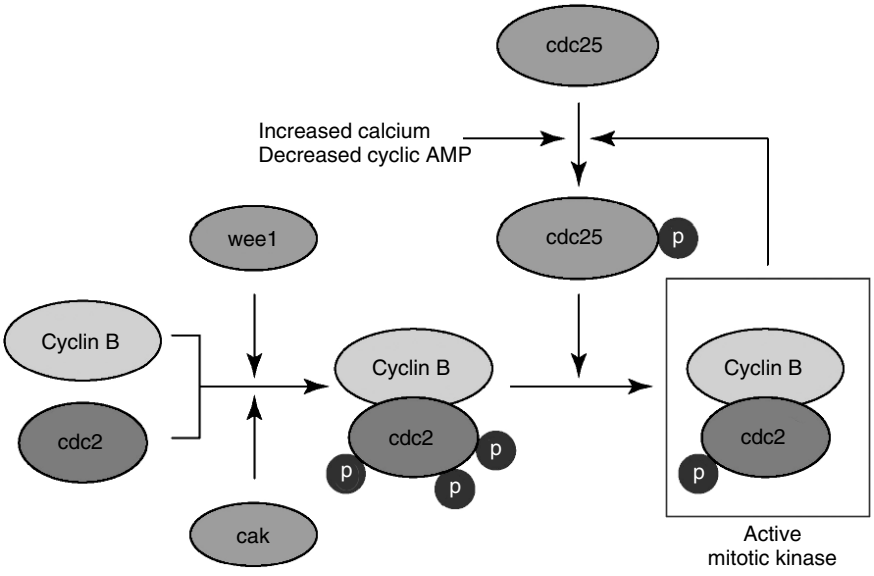

Fig. 11 Activation of mitotic kinase by the cdc25 phosphatase. Cdk activating kinase (cak) and wee1 kinase phosphorylate the cdk1/cyclin complex. Cak phosphorylation activates the mitotic kinase and wee1 phosphorylation is inhibitory. Cdc25 phosphatase removes the inhibitory phosphates. Cdc25 is controlled by cAMP and calcium.

5.4 The Checkpoint at Cell Cycle Onset

There are analogies between fertilization in species such as echinoderms that are fertilized in G1 and the G1 decision point in mammalian somatic cells. One striking example is starfish oocytes: if they do not sense a fertilization calcium transient, they proceed to apoptosis. Other similarities are the activation of an MAP kinase signaling cascade, stimulation of the sodium-hydrogen antiporter by protein kinase C, and stimulation of the protein synthetic machinery. Nonetheless, the comparison is less precise at the molecular level.

5.5 Calcium and Cell Cycle Checkpoints

The existence of identical molecular mechanisms in arrested oocytes and in the checkpoint mechanisms of somatic cells strongly suggests that the arrest before fertilization uses the checkpoint machinery and raises a question: is calcium signaling a component of general cell cycle regulation or is control of the checkpoint machinery by calcium unique to fertilization?

That calcium is a cell cycle regulatory signal is clear in some cases, and less clear in others. In some embryos, calcium signals can be identified at the times at which the checkpoint mechanisms operate; the amplitude of the signals is small, less than one-tenth of the size of the fertilization calcium signal and signals are often local to the nucleus. The calcium-calmodulin-calmodulin kinase II pathway has been shown to control entry into mitosis and calcium and calmodulin control separation of the chromosomes at mitosis. Embryos do not possess a G1 decision point mechanism.

In somatic cells, it has been shown, for example, that calmodulin-dependent protein kinase II must be activated at mitosis entry and that it phosphorylates cdc25, the activator of cdk1/cyclin B. It has also been shown that rapidly raising intracellular calcium can induce anaphase. Checkpoint-associated calcium signals can be detected, but they are not present in all circumstances. The jury is out on the universality of cell cycle calcium signaling, but if the hypothesis turns out to be true, then the calcium signals central to fertilization will have pointed the way.

Keywords

Activation
Stimulation of cells to undergo partial, selective, or complete synthesis and secretion of mediators, or generation of other molecules or responses in response to a variety of triggers; such processes may be associated with subtle morphologic changes discernible only by appropriate ultrastructural studies.

Corticotropin-releasing Hormone
A peptide originally shown to be secreted from the hypothalamus in response to stress and primarily stimulating the anterior pituitary cells to secrete ACTH. It has since been shown to affect numerous systems including the immune system, and we proposed that it be renamed ''stress response hormone (SRH)'' instead of CRH.

Degranulation
The release of the contents of secretory granules, from mast cells or other secretory cells such as polymorphonuclear leukocytes, platelets, pituitary, or β-pancreatic cells in response to specific receptor-mediated triggers through a process dependent on energy and extracellular calcium ions.

Inflammation
An orchestrated, often excessive response of the organism, involving the immune, endocrine, and neural systems against real or perceived triggers.

Protease-activated Receptors (PARs)
Unique receptors on cell surfaces, stimulation of which leads to widespread inflammation.

Stress
The response of cells and tissues to real or perceived noxious stimuli with anti-inflammatory effects through brain secretion of CRH, but proinflammatory effects through peripheral secretion of CRH and related peptides.

Tryptase
One of many unique proteases secreted from mast cells that have multiple actions, such as microvascular leakage, stimulation of protease-activated receptors (PARs) and induction of inflammation, generation of active peptides, degradation of cytokines.

Inflammatory arthritis is a highly prevalent condition with substantial morbidity and degree of disability. The pathogenesis is still poorly understood limiting effective therapy. Increasing evidence has implicated synovial mast cells in the initiation of inflammatory arthritis. Mast cells are commonly known for their involvement in allergic reactions through degranulation and release of histamine. However, these cells are capable of releasing over 50 potent vasoactive, proinflammatory and neurosensitizing molecules in response to nonallergic triggers without degranulation. Such selective release of cytokines, especially in response to stress hormones, provides a unique explanation and possible therapeutic targets for inflammatory arthritis.

1
Osteoarthritis Versus Rheumatoid Arthritis

A 2002 report from the US Center for Disease Control (CDC) indicated that one-third of all adults in the United States (almost 70 million) suffer from arthritis or chronic joint pain, up from one-fifth in 1993, with an estimated annual cost of $82 billion. The impact of arthritis is comparable in Australia, Canada, Europe, and the United Kingdom, with an estimated total of another 60 million affected individuals.

Osteoarthritis (OA) is a degenerative joint disease and is characterized by the breakdown of the joint's cartilage and loss of joint space especially in hands and weight-bearing joints, such as knees, hips, feet, and the back. Cartilage breakdown allows bones to rub against each other, causing inflammation, pain, and loss of movement. Although age is a risk factor, obesity, and joint injuries due to sports, work-related activity, or accidents increase the risk of developing OA.

Rheumatoid arthritis (RA) involves chronic inflammation and destruction of the joints. RA is a systemic disease that affects the entire body and is characterized by inflammation and reactive hyperplasia of the synovium, which causes redness, swelling, stiffness, and pain. RA typically affects many different joints and is noted for remissions and flares, often precipitated or exacerbated by stress. Articular damage in RA involves cartilage erosion, inflammatory cell accumulation and finally to bone destruction and reactive bone spur formation. The involved joints lose their shape and alignment, resulting in pain and loss of movement.

1.1
Specific Triggers Versus Lack of Inhibitory Molecules

As in common practice in medicine, there have been numerous investigations in the potential trigger(s) implicated in the pathophysiology of inflammatory and especially of rheumatoid arthritis. In certain cases, as in crystal (gout) arthritis or Lyme arthritis, the etiologic agents are known. However, such triggers are not known for RA. There is some evidence from animal models that inflammatory arthritis may involve an inappropriate autoimmune response against structural (colagen) or infection (bacterial, viral) antigens. However, little attention has been paid to the potential lack of innate inhibitory molecules, such

as a_1-antitrypsin or a_2-macroglobulin in other tissues.

2 Mast Cells in the Joints

The inflammatory and subsequent lytic processes in inflammatory arthritis are not well understood, especially the initial triggering events. Until recently, discussion of the cellular elements involved did not even mention mast cells, even though a number of papers had reported the presence of mast cells in joints. Over the last 10 years, histochemical observations were correlated to clinical findings. Increased numbers of mast cells have been routinely noted and their mediators could initiate and promote inflammation while mast cells constitute a small fraction of the cells in a normal human synovium, they increase to almost 10% in RA. Mast cells, cytokines, and metalloproteinases were colocalized in the RA lesion and activation of synovial mast cells was shown to be autoregulated by their own mediators' histamine and tryptase (Fig. 1).

It was recently convincingly argued that mast cells may be involved in inflammatory arthritis; however, this presentation was still limited primarily to the role of histamine and tumor necrosis factor, TNF-α, and did not discuss potential triggers such as C3a and C5a. One of the reasons why mast cells have been neglected comes from the persistence of associating them only with allergies in spite of mounting evidence to the contrary. Another reason is the fact that mast cells are not commonly seen to degranulate in tissues such as joints that do not get allergic reactions; they were, therefore, considered an ''innocent bystander's'' renewed evidence that mast cells can release mediators selectively without degranulation, especially in response to nonallergic triggers (discussed in the following) has expanded the potential importance of mast cells.

2.1 Inflammatory Mediators

Mast cell-derived TNF-α mediates inflammation and induces hypertrophy of draining lymph nodes during infection.

Mast cells are known to secrete IL-6 and recent studies showed that mast cell–deficient mice could not increase their serum IL-6 in response to acute stress. This is of interest in view of the fact that IL-6 is elevated, especially in juvenile RA. IL-6 is

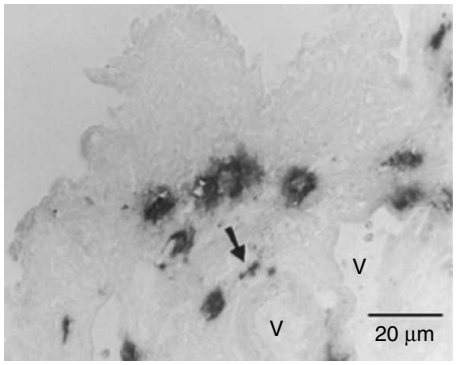

Fig. 1 Tryptase-positive mast cells (brown color) adjacent to blood vessels (V) from the joint of a patient with rheumatoid arthritis (See color plate p. xxxviii).

also important in collagen-induced and antigen-induced arthritis.

A number of chemokine receptors have also been identified on mast cells, especially CXCR3 protein, which was preferentially expressed on mast cells in the synovium of RA patients.

3 Chemoattractants

Tryptase can cause microvascular leakage and stimulate protease-activated receptors (PAR) leading to widespread inflammation, including autocrine stimulation of mast cells. Protease also acts as a tissue metalloproteinase, degrading matrix, as well as gelatinase, thus contributing to tissue remodeling. Tryptase also induces hyperexcitability of submucosal neurons, while histamine directly stimulates SP and calcitonin gene-related peptide (CGRP)-containing neurons of the trigeminal system.

Cells obtained from fluid aspirated from joints of patients with arthrosynovitis express RANTES and MCP-1, both of which are potent mast cell chemoattractants. In addition, stem cell factor (SCF) and nerve growth factor (NGF) are also known to induce mast cell migration, proliferation, and secretion. Other mast cell chemoattractants include vascular endothelial growth factor (VEGF), epidermal growth factor (EGF), and platelet-derived growth factor (PDGF).

3.1 Animal Models

In spite of the fact that TNF blockers are used clinically with considerable success in adult RA, increasing evidence indicates that IL-6 may be equally or more important. In fact, we recently showed that experimental inflammatory arthritis in mice was unaffected in TNF −/− mice. Instead, the IL-6 −/− mice were resistant to inflammatory arthritis, and humanized antibody to human IL-6 receptor inhibited collagen-induced arthritis. These findings are of particular significance as we recently showed that mast cells are the sole source of serum IL-6 elevations induced by acute stress in mice. Most recently, mast cell deficient mice were shown to be resistant to autoimmune and inflammatory arthritis.

In particular, inflammatory arthritis induced by the injection of carrageenan in the hind knee joints, increased the joint size by 1.94 ± 0.41 mm in C57BL mice in 4 days, by which time the mice were obviously limping (Fig. 2). These effects were inhibited in W/W^v mast cell deficient and corticotropin-releasing hormone (CRH) −/− mice, which were clinically indistinguishable from mice injected with normal saline (Fig. 2). These results are of interest because CRH is increased in the joints of RA patients and CRH receptors (CRHR) are present on articular mast cells, implying that CRH could trigger or regulate mast cell activation. In fact, we showed that CRH could activate mast cells in the skin and increase vascular permeability in rodents. CRH was recently shown to also induce mast cell–dependent vascular permeability in humans. The pathophysiological implication of such finding is that CRH could be released locally under stress and could exacerbate inflammatory diseases (Fig. 3).

It is quite interesting that stress increased serum IL-6 levels in care givers of chronically ill patients, but it was decreased in those who went to church regularly, indicating that reduction of stress could lead to decrease in a key proinflammatory cytokine producer.

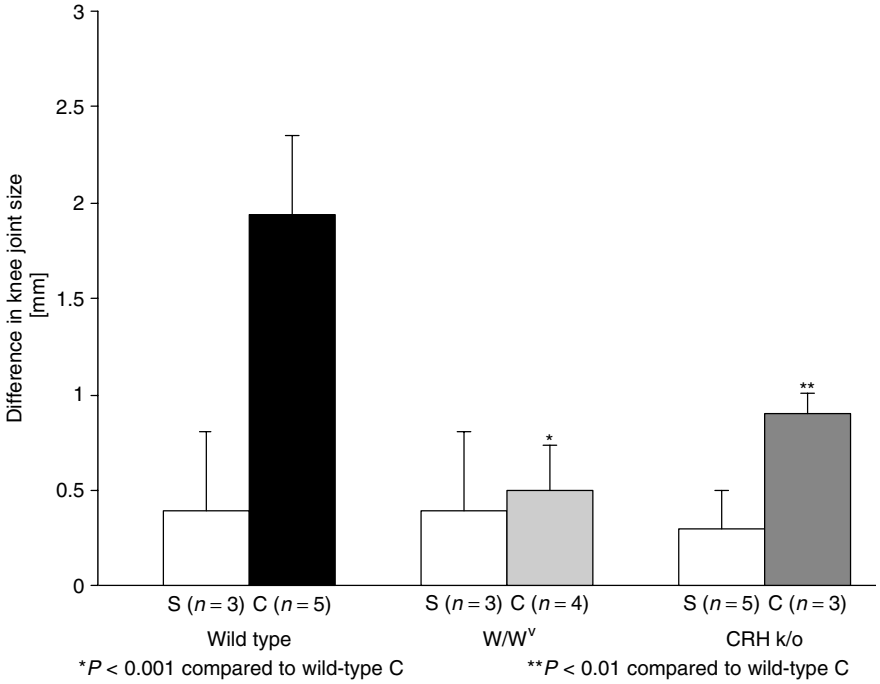

Fig. 2 Lack of inflammatory arthritis in W/W^v mast cell deficient and CRH −/− mice. W/W^v = mast cell deficient mice; k/o = knockout mice; S = normal saline; C = carrageenan.

The K/BxN mouse has been used as a model for human inflammatory arthritis and it was recently shown that the presence of autoantibodies against glucose-G phosphate isomerase is dependent on mast cells.

4 Pathophysiology of Mast Cells

Mast cells derive from a bone marrow progenitor and mature in tissues depending on microenvironmental conditions; they are characterized by the surface expression of the stem cell factor (CSF) receptor c-kit and the high affinity receptor for immunoglobulin E (FcεRI). Mast cells are important not only for allergic reactions but also in inflammation, autoimmunity, and inflammatory arthritis. However, though mast cells do not always express their c-kit receptor or FceRJ, they do so during inflammation. They are ubiquitous in the body, including the brain and joints that are not known to develop allergic reactions. Mature mast cells vary considerably in their cytokine and proteolytic enzyme content. However, the phenotypic expression of mast cells does not appear to be fixed.

In fact, mast cells cultured together with pheochromocytoma cells were shown to develop contacts with the latter and acquire the ability to respond to neuropeptides.

4.1 Triggers

In addition to IgE and antigen, anaphylatoxins, C3a, C5a antibody light chains, bacterial or viral superantigens aggregated

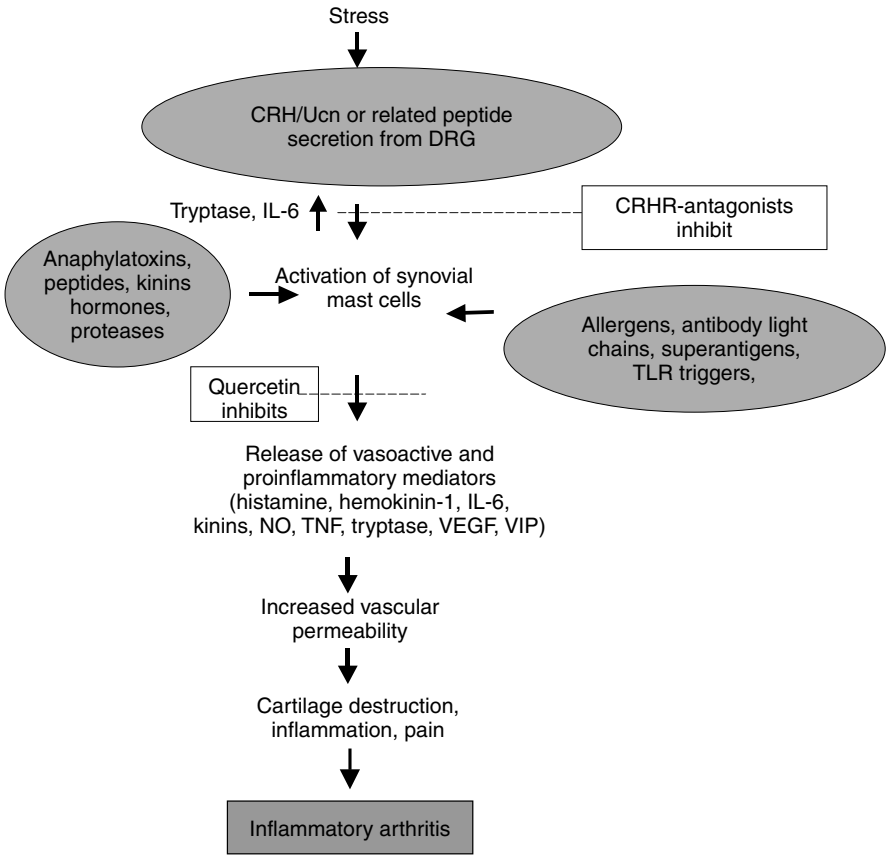

Fig. 3 Schematic representation of the possible role of mast cells in inflammatory arthritis. DRG = dorsal root ganglia; NO = nitric oxide; VIP = vasoactive intestinal peptide; VEGF = vascular endothelial growth factor.

IgG cytokines, histamine-releasing factors, hormones, and neuropeptides can trigger mast cell secretion (Table 1). The latter include SP, somatostatin, neurotensin (NT), parathyroid hormone, and NGF, which is also released under stress.

Mast cells can also be activated by endothelin, and blockade of the endothelin receptor was recently shown to block *in vivo* effects attributed to mast cells in mice. Proteases released from mast cells or other inflammatory cells can generate biologically active peptides, like histamine-releasing peptide (HRP) from plasma albumin, and HRP is found in synovial fluids obtained from patients with RA. Adherent *Escherichia coli* can activate mast cells that express Toll-like (Toll) receptors 2, activated by *E. coli* lipopolysaccharide (LPS); such receptors are critical in innate and acquired immunity.

4.2 Mediators

Mast cells synthesize and secrete over 50 biologically potent molecules that include most of the known cytokines. They

Tab. 1 Triggers of mast cell activation.

Antigens	***Hormones***
Allergens/IgE	ACTH
Aggregated IgE	CRH
Antibody light chains	Estradiol
Chemokine receptor ligands (CXCR3)	PTH
Superantigens (bacterial, viral)	Urocortin
Toll-like receptor (TLR 2, 4, 9) triggers (LPS, PDG, dd DNA)	*Peptides*
	Albumin-derived histamine-releasing molecules
Anaphylatoxins	Bradykinin
C3a, C5a	CGRP
	Endorphins
Cytokines	Endothelin

Notes: dd: double stranded; LPS: lipopolysaccharides; PDG: peptidoglycan; TLR: Toll-like receptor.

can, therefore, easily induce vasodilation, vascular endothelial molecule expression, and chemoattraction, which is necessary for the initiation of inflammation.

These vasodilatory, angiogenic, proinflammatory, and neurosensitizing mediators (Table 2) include histamine, heparin, kinins, neuropeptides such as vasoactive intestinal peptide (VIP) and proteases, such as chymase and tryptase (preformed) as well as chemoattractants, cytokines, growth factors, leukotrienes, prostaglandins, nitric oxide (NO), SCF, and VEGF (newly synthesized) (Table 2).

The most abundant mediators are proteases that can cause microvascular leakage, activation of PAR receptors and inflammation, as well as activation of neuropeptide precursors and direct proteolytic damage to synovium. Mast cells are also particularly rich in TNF-α and IL-6 both of which are implicated in arthritis, as discussed earlier. Mast cells are also the richest source of CRH outside the brain and could help propagate local inflammatory processes in response to chemical, mechanical, or oxidative stress.

Tab. 2 Mast cell mediators and their biologic effects.

Molecules	***Major actions***
Prestored	
Enzymes	
Arylsulfatases	Lipid/proteoglycan hydrolysis
Carboxypeptidase A	Peptide processing

INF-α; MIF; TNF-α	Inflammation, leukocyte proliferation/activation
Growth Factors	
CSF, GM-CSF, β-FGF, NGF, VEGF	Endothelial, immune and neuronal cell growth

4.3 Selective Secretion

One of the reasons mast cells have remained fairly obscure in inflammatory arthritis has been the fact that they appear "intact," giving the impression that they are quiescent.

Unlike degranulation, where most of the 500 secretory granules, each 1000 nm in diameter release their contents in an explosive manner, mast cells can undergo

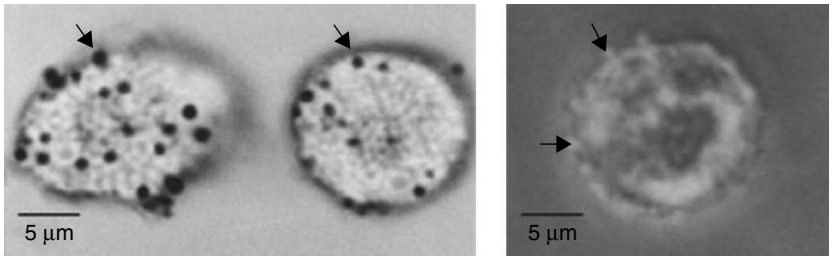

Fig. 4 Punctate release of contents of individual secretory granules from purified rat peritoneal mast cells incubated with calcium containing liposomes. (a) Content of individual granules (arrow) visualized by ruthenium red staining (with a complementary filter to show black) using Nomarski optics; (b) individual granules in the process of exocytosis from a mast cell visualized by ruthenium red staining.

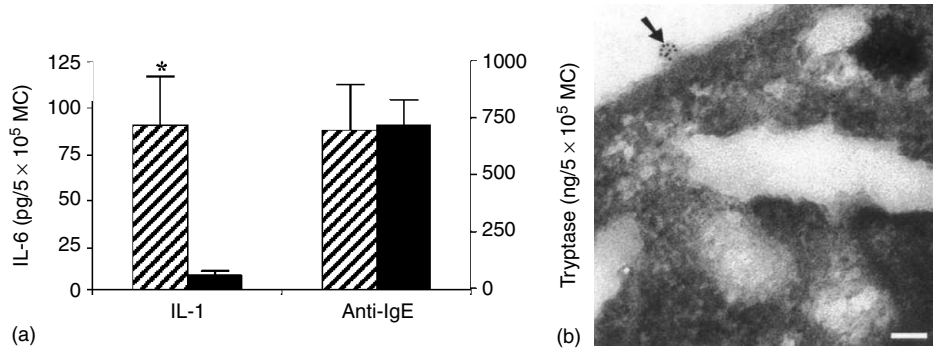

Fig. 5 Selective vesicular IL-6 release induced by IL-1 from normal human cultured mast cells. (a) IL-6 and tryptase release in response to either IL-1 or anti-IgE ($n = 8$ $^*p < 0.05$); (b) a vesicle (arrow) budding from a mast cell observed by cryo-immuno-ultrastructural microscopy "white" areas represent secretory granules. Scale bar = 70 nm.

secretion of the content of individual granules (Fig. 4).

Mast cells also have the ability to release some mediators selectively without degranulation. This unique phenomenon has been shown for biogenic amines, eicosanoids, and IL-6. In fact, IL-1 was shown to induce selective release of IL-6 without histamine or tryptase, through a process that involves small vesicles (50–70 nm each in diameter) (Fig. 5). Mast cells *in vivo* also often have ultrastructural alterations of their electron dense granular core indicative of secretion, but without degranulation, a process termed *activation*, or *intragranular activation*, or *piecemeal* degranulation. This appearance was prominent in brain mast cells of nonhuman primates with experimental allergic encephalomyelitis (EAE), and in human inflammatory conditions such as inflammatory bowel disease (IBD) or interstitial cystitis (IC) of the urinary bladder. Moreover, in certain diseases such as

scleroderma and IC, mast cells appear totally depleted of their granule content and they could not be recognized by light microscopy (phantom mast cells).

Unpublished evidence indicates that synovial mast cells in RA undergo mostly selective release of mediators that is not obvious by routine histopathology.

5
Neurohormonal Stimulation of Mast Cells and Inflammatory Disorders

Mast cells could also be activated by antidromic nerve stimulation as shown for trigeminal or cervical ganglion stimulation that may result in neuropeptide secretion of reactive fibers when localized close to mast cells, release of SP from sensory afferents could stimulate mast cell secretion *in vivo*. NT also could be released from dorsal root ganglia (DRG) alone or together with CRH and further stimulate mast cells.

5.1
Anatomical Observations

Mast cells are located perivascularly in close proximity to neurons. A functional association between mast cells and neurons has been reported in 1999, and the potential pathophysiological role of brain mast cells has been reviewed by Theoharides in 1996.

5.2
Stress and the HPA Axis

Chronic stress affects illness and suppresses the immune system. Acute stress, however, can exacerbate inflammatory syndromes. In fact, there is evidence that acute stress can stimulate the immune system. Stress has been shown to worsen arthritis and activate mast cells.

Corticotropin-releasing hormone or CRH is a 41-amino acid peptide that regulates the hypothalamic-pituitary adrenal (HPA) axis and coordinates the stress response through activation of the sympathetic nervous system. CRH acts through specific receptors, which include CRHR-1 and CRHR-2. Both receptor types are located on brain neurons, but CRHR-2 has also been identified on cerebral arterioles that could be stimulated by CRH and urocortin (Ucn) directly. CRHR-2 has been further subdivided to CRHR-2α and CRHR-2β, which are best activated by Ucn, a peptide with about 50% structural similarity to CRH; Ucn II and Ucn III have also been identified and are potent CRHR-2 agonists.

5.3
Proinflammatory Effects of Stress

Both CRH and CRH mRNA have been demonstrated in rodent spleen and thymus, while human peripheral blood leukocytes and enterochromaffin cells express mRNA for Ucn. CRH and CRHR mRNA is expressed in rodent and human skin, CRH-like immunoreactivity is present in the dorsal horn of the spinal cord and in DRG, as well as in sympathetic ganglia. We recently showed that acute stress could increase the skin content of CRH, most likely from DRG. We also showed that human mast cells contain both CRH and Ucn that could be released in response to immunologic stimulation.

CRH can stimulate leukocytes to produce β-endorphin, adrenocorticotropic hormone (ACTH), and α-melanocyte stimulating hormone (α-MSH), as well as monocytes to secrete interleukin-1 (IL-1), and lymphocytes to produce IL-2.

CRH also stimulated lymphocyte proliferation, increased IL-2 receptor expression on T lymphocytes, was chemotactic for mononuclear leukocytes and activated CRHR-1 on spleen cells.

Relevant examples of possible proinflammatory actions of CRH include carrageenan-induced aseptic inflammation and arthritis, where both CRH and Ucn have been identified in the joints. Moreover, inflammatory arthritis shown to be absent in W/W^v mast cell deficient mice, was blocked by the preferential CRHR-1 antagonist Antalarmin and was greatly attenuated in CRH knockout mice. In fact, mast cells in the joints of RA patients were reported to express CRH receptors.

5.4 CRH Effects on Mast Cells

Mast cells are localized close to CRH positive neurons in the rat median eminence. CRH administration in humans causes peripheral vasodilation and flushing reminiscent of mast cell activation. Iontophoresis of CRH increased human skin vasodilation, detected by laser Doppler, which was dependent on CRHR-1 and mast cells. Intradermal CRH administration leads to histamine-dependent swelling; in rodents, intradermal CRH leads to activation of mast cells and Evans blue extravasation was also induced. Moreover, CRHR-1 is involved in stress-induced exacerbation of chronic contact dermatitis in rats.

In addition to CRH stimulating mast cells, mast cell mediators could influence CRH release. For instance, human mast cells synthesize and secrete large amounts of CRH. Histamine can increase CRH mRNA expression in the hypothalamus, and mast cells could stimulate the HPA axis. This could occur possibly through IL-6 and IL-1, both of which are released from mast cells; conversely, CRH stimulates IL-6 release. Acute stress also increased BBB permeability in rats and mice only in brain areas containing mast cells.

CRH Ucn can directly activate mast cells that express CRHRs; in fact, mast cells were recently shown to express five CRHR-1 isoforms that could have different functions.

6 Therapy

Typical therapy for osteoarthritis involves weight loss, exercise, and use of nonsteroidal anti-inflammatory drugs (NSAIDs). In RA, active articular inflammation often requires immunosuppressant and immune modifying drugs. Severe RA requires multiple agents that include steroids, methotrexate, penicillamine, gold salts, and most recently TNF blockers, such as etanercept or infliximab. Unfortunately, recent evidence that cyclooxygenase 2 (COX-2) inhibitors increase cardiovascular disease has forced the withdrawal or limited use of such drugs.

Except for glucocorticoids, there are no clinically effective mast cell inhibitors.

6.1 Proteoglycans

Glucosamine sulfate presumably acts as a building block for new cartilage, while chondroitin sulfate acts as a "ready-made" component.

D-Glucosamine, *N*-acetylglucosamine, glucosamine sulfate, and chondroitin are commonly used for arthritis. A meta analysis of clinical trials using glucosamine

and/or chondroitin originally had indicated potential usefulness in OA. The validation of WOMAC, a self-administered health status instrument for OA has helped with the design of double-blind studies; similarly the Cedars–Sinai Health Related Quality of Life Instrument (CSHQ-RA) can be used for RA research. One of the first double-blind studies compared 500-mg glucosamine sulfate tid to 400-mg ibuprofen tid for 4 weeks. From the second week onwards, the clinical improvement was the same (~50%) in both groups, but 35% of those on ibuprofen reported adverse effects as compared to 6% on glucosamine. At least two studies have shown that 1500 mg of glucosamine per day for 3 years can delay progression of OA and knee space reduction. In another randomized, double-blind placebo-controlled trial, 212 patients with OA of the knee were assigned either 1500 mg of oral glucosamine sulfate or a placebo for 3 years. Patients on active treatment had clinical improvement of symptoms and no significant joint space loss, compared to progressive narrowing of those on placebo. In a subsequent study, 202 patients with OA of the knee were randomized to either 1500 mg of glucosamine sulfate or placebo for 3 years; symptoms on the active group improved by about 25% and joint space narrowing (>0.5 mm) occurred in 5% of those on the active arm as compared to 15% on the placebo. However, more recent studies with glucosamine, especially when administered for shorter duration, have failed to show consistent benefit. Moreover, use of 1500 mg of glucosamine per day could interfere with insulin sensitivity.

The proteoglycan chondroitin sulfate has also been added to glucosamine, but there are a number of problems with such preparations. Very little oral chondroitin sulfate is absorbed in powder form due to its high molecular weight (150 000–1 000 000 Da) and degree of sulfation. In particular, less than 5% of chondroitin sulfate is absorbed intact when administered orally. In another study, after oral intravenous administration of chondroitin sulfate (16 000 Da), the absolute bioavailability was 13%, but when chondroitin sulfate of about double the size (26 000 Da) was used, less than 4% of the oral dose administered in rats was intact chondroitin sulfate in the blood. However, the smaller size (16 000 Da) has almost no protective value in laboratory experiments. Other papers found no oral absorption of chondroitin sulfate and concluded that any protective effect in the joints after oral administration was unfounded.

There are no good studies on the use of proteoglycans in RA, presumably because the aim has traditionally been the synovial inflammatory response. However, chondroitin sulfate was shown to inhibit activation of connective tissue mast cells. There is also some evidence that bacterial adhesion and invasion depends on sulfated surface polysaccharides and use of chondroitin sulfate as ''decoy'' may prevent bacteria from adhering to the cell surface and causing infection. Aloe vera has been reported to reduce mast cell secretion and mast cell infiltration in an inflamed synovial pouch model.

6.2 Flavonoids

Few clinically available drugs can effectively inhibit human mast cell activation. For instance, even though disodium cromoglycate (cromolyn) had been known to inhibit activation of rodent mast cells, it was unable to inhibit human mast cell activation. The most well documented evidence published to date on the inhibitory

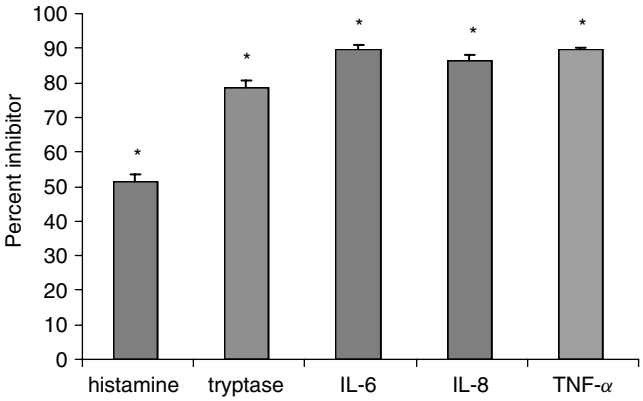

Fig. 6 Inhibitory effect of quercetin on normal human mast cell proinflammatory mediator secretion. Mast cells were sensitized with human-IgE and was pretreated for 15 min prior to stimulation with anti-IgE (10 μg mL^{-1}) for 30 min (histamine, $n = 6–31$; and tryptase, $n = 6–16$) and for 6 h (IL-6, IL-8, and TNF-α, $n = 4–7$) at 37 °C. Quercetin significantly inhibited all these mediators when compared to anti-IgE alone treated mast cells. $* = p < 0.05$.

action of mast cells has focused on the naturally occurring flavonoids. For instance, quercetin can inhibit not only the prestored mediators histamine and tryptase from normal human mast cells but also the synthesis of the cytokines IL-6, IL-8, and TNF-α (Fig. 6).

Some flavonoids like morin have weak inhibitory activity, even though it differs from quercetin on the addition of one hydroxyl group in the β-phenolic ring.

6.3 Synergistic Effects

However, chondroitin sulfate appears to block mast cell activation and histamine release; quercetin blocks mast cell secretion and particularly cytokine secretion. The two molecules together could have synergistic actions. Patients do not have an allergic reaction to glucosamine sulfate or chondroitin sulfate if they are allergic to sulfonamide antibiotics. Rutin, the glycoside form of quercetin, also has antiarthritis properties.

The possibility is rather unlikely, because there was absence of cross-reactivity between sulfonamide antibiotics and sulfonamide nonantibiotics.

7 Perspectives

Evidence dating back over 20 years that mast cells may participate in inflammation through selective release of proinflammatory molecules had been ignored until recently (see Figure 7). It now appears that mast cells are critical for the initiation of inflammation, especially in arthritis. Unfortunately, the triggers of synovial mast cell activation are not known and there are no clinically available mast cell inhibitors.

A combination of proteoglycans and select flavonoids, such as quercetin (e.g. ArthroSoft®) together with low dose buffered salicylates, (e.g. Trilisate) may

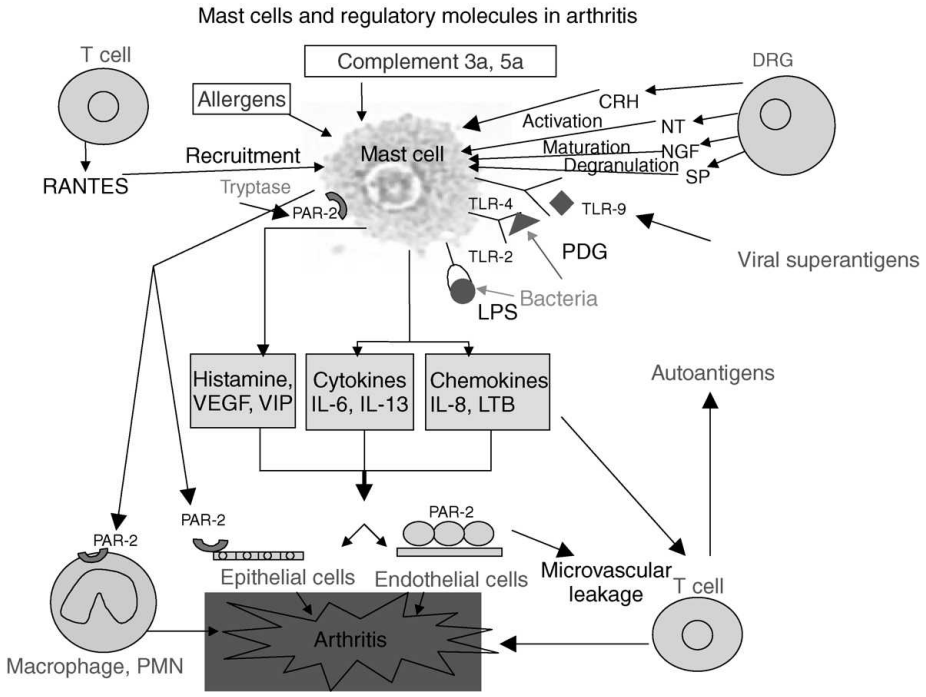

Fig. 7 Diagrammatic representation of synovial mast cells interaction with other cells in the initiation of synovial inflammation and arthritis.

be the best initial approach for RA. The additional benefit of quercetin is its unique ability to inhibit secretion of many proinflammatory molecules, especially IL-6 that has been increasingly implicated in juvenile RA. Such molecules could be combined with CRH receptor antagonists when they become clinically available.

Acknowledgment

Aspects of our own research have been funded by NIH grants No. DK 42409, DK 44816, DK 62861, NS38326, and AR47652. Use of CRH receptor antagonists, as well as proteoglycans and flavonoids, for inflammatory conditions is covered by US patents # 6,020,305; 6,624,148; # 6,635,625; 6,641,806; 6,645,482; 6,689,748 and 09/771,669 (allowed Aug 10, 2004) awarded to TCT and assigned to Theta Biomedical Consulting and Development, Co., Inc. (Brookline, MA). Thanks are due to Dr D. Kempuraj and Dr N. Papadopoulou, as well as to Mrs. Jill Donelan and Mrs. Jessica Christian for some of the graphics, and to the latter also for her patience and word processing skills.

Keywords

Azapeptides
Peptide mimetics in which one or more amino acid residues is (or are) replaced by azaamino acid(s) (i.e. amino acid(s) where the carbon atom bearing the amino group is replaced by nitrogen).

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 14

Aminooxy Peptides
Analogs of β-, γ- or δ-peptides in which the β-, γ- or δ-carbon is replaced by an oxygen atom.

Oligocarbamate
A compound containing repeating O−CO−NH units separated by two carbon atoms, one of which may bear a side chain.

Oligourea
A compound containing repeating NH−CO−NH units separated by two carbon atoms, one of which may bear a side chain.

***β*-,*γ*-, *δ*-, *ε*-Peptides**
Peptide mimetics based on β-, γ-, δ- or ε-amino acids.

Peptide Mimetics (or Peptidomimetics)
Compounds imitating the structure of bioactive peptides, preserving overall conformational features and retaining some of the chemical groups that interact with biological targets, but incorporating nonamino acid units.

Peptoids
Peptide mimetics in which the amino acid side chains are shifted to the amide nitrogen atoms.

Very many peptides have the potential of being used as drugs. Nevertheless, they usually suffer from serious limitations stemming from their metabolic lability and unfavorable pharmacokinetics. A promising approach to circumvent these problems is the use of conformationally similar molecules, able to interact with the same biological targets, but less susceptible to metabolic degradation and with better absorption and distribution properties. This may be achieved through the synthesis of peptide mimetics where some or all of the amino acid residues have been replaced by different chemical moieties. This article gives a brief overview of peptide mimetic structures on which medicinal chemists have focused in the last few years, together with the chemical approaches used for their synthesis and of the amino acid replacements that serve as their building blocks. These methods range from classical organic synthetic methods to quite sophisticated catalytic and solid-phase protocols.

In many cases, the target compounds have been tested in biological systems with varying degrees of success. These results should not be construed as an indication of unreliability of the peptidomimetic approach, but rather as a reflection of the limited sample examined to date. Because of the solid foundations on which this therapeutic strategy is based, we think that a growing number of peptide mimetics are likely to enter the clinic in the coming years.

1 Introduction

The large number of endogenous peptides that act as cytokines, hormones, or neurotransmitters, in the regulation of neural function and blood pressure, and in inflammation, continues to increase. Not only are primary gene products important, but in many cases their breakdown also affords smaller peptides with increased potency or with qualitatively different properties. Nevertheless, the development of clinical therapies based on endogenous peptides has been rather intuitive and not actually realized because of pharmacokinetic as well as pharmacodynamic issues, which seem to be difficult to solve properly. In order to overcome these drawbacks, the discovery by screening, the design, synthesis, and pharmacological testing of nonpeptide ligands of peptide receptors – either as agonists or antagonists – has become a very active field, particularly during the last decade.

Peptide mimics, peptide mimetics, or peptidomimetics may be defined as compounds that can substitute for peptides in their interactions with receptors or enzymes. Early examples such as morphine – a mimic of opioid peptides – did not result from any awareness of their mechanism of action. More recently, screening efforts have led to ''hits'' such as the natural, moderately potent cholecystokinin receptor antagonist asperlicin, described by Chang et al. in 1985, which has been modified to afford a plethora of synthetic analogs based on either the 1,4-benzodiazepine or the quinazolidinone moieties, reviewed by Herranz in 2003, in both of which series peptide analog portions may be discerned.

The design, synthesis, and evaluation of peptide mimics dates back at least to the late 1960s, but the vast majority of papers in the field are less than 20 years old, and the number of publications in the last decade is close to three-quarters of the total. The subject of peptide mimics can be divided into three major areas: modifications of the amino acid side chains, modifications of the peptide backbone, and dipeptide mimics with constrained conformations. The first aspect has been addressed by Williams in the previous edition of this encyclopedia (1996), and will not be considered here. Isosteric replacements of the peptide bond (CONH) by groups such as thioamido (CSNH), ester (COO), ketomethylene ($COCH_2$), methyleneoxy-, methylenethio-, or methyleneamino (CH_2O, CH_2S, CH_2NH), retro-amido (NHCO), or trans C=C double bonds (CH=CH, CF=CH) were reviewed by Goodman and Ro in 1995 in a chapter of Burger's Medicinal Chemistry that is more concerned with conformationally constrained dipeptide mimics. These are a newer development that relies heavily on a firm understanding of protein conformation, which has been reviewed by Hruby and Balse in 2000. Another review volume is that of Abell in 1999. An extensive, five-volume treatise on the subject of peptide and peptidomimetic synthesis was published by Goodman et al. in 2002, and again, as a ''workbench edition,'' in 2004. We will consequently concentrate on advances made in the last few years.

The synthesis of these compounds relies in part on classical peptide chemistry, but almost always incorporating specific modifications to accommodate the different building blocks required. An important general methodology for the construction of peptoids, for example, is the approach of Zuckermann, described below, which continues to be used in most cases.

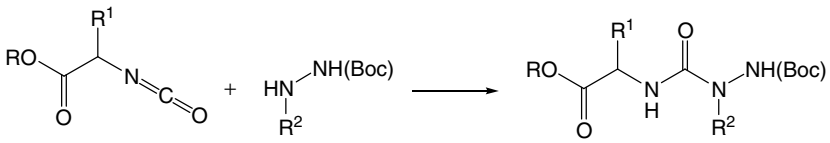
2 Azapeptides

Azapeptides are peptide mimics in which one or more backbone α-carbon atoms have been replaced by nitrogen. From the structural standpoint, this means introducing one or more urea moieties in the peptide chain. Occasional syntheses of monoazapeptides have been described at least for the last 40 years and were reviewed as far back as 1970. However, this type of peptide mimic was not included in the Goodman and Ro chapter published in 1995, although it has been reviewed in 2002 by Zega and Urleb, so we will discuss them in some detail.

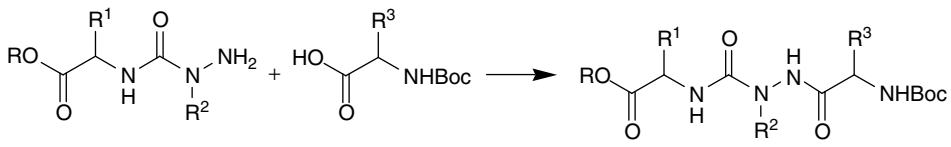
Azapeptide synthesis has generally been achieved by a combination of hydrazine chemistry and peptide chemistry. For example, the reaction of a 1-alkyl-2-Boc-protected hydrazine or an unprotected monoalkylhydrazine with a carboxylic acid ester α-isocyanate affords an N-protected or unprotected monoazadipeptide derivative (Scheme 1). Even in unprotected monoalkylhydrazines, reaction at thesubstituted nitrogen atom is favored. If deprotected, the resulting semicarbazide can be coupled to the carboxyl group of an N-protected amino acid or peptide using, for example, conventional dicyclohexylcarbodiimide (DCC) coupling, to provide the elongated product (Scheme 2).

A stepwise example of this, requiring purification at each step, but which resulted in potent, selective cysteine protease inhibitors, is that of Wieczerzak et al. in 2002. In this case, peptides were prepared in solution and then an azaglycine residue was appended to the free amino group by coupling *t*-butyl carbazate (Boc-hydrazine) and an amino acid or peptide ester or amide with carbonyldiimidazole, where the key reaction is shown in Scheme 3. Although experimental details are lacking, the Boc-azapeptide could presumably be deprotected and coupled to a Boc-protected amino acid or peptide using conventional methodology (the use of 2-(1-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium tetrafluoroborate – TBTU – or DCC, and 1-hydroxybenzotriazole – HOBt – are mentioned).

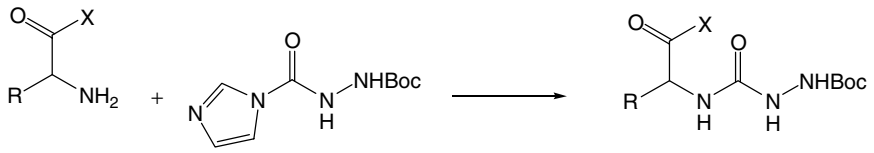
The synthesis of a series of Boc-protected alkylhydrazines was described by Dutta and Morley in 1975, and still constitutes a generally useful approach. This is



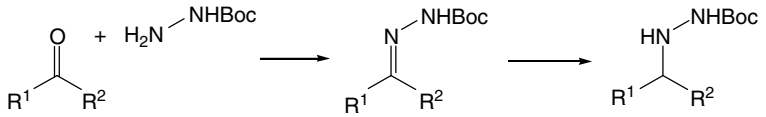
Scheme 1



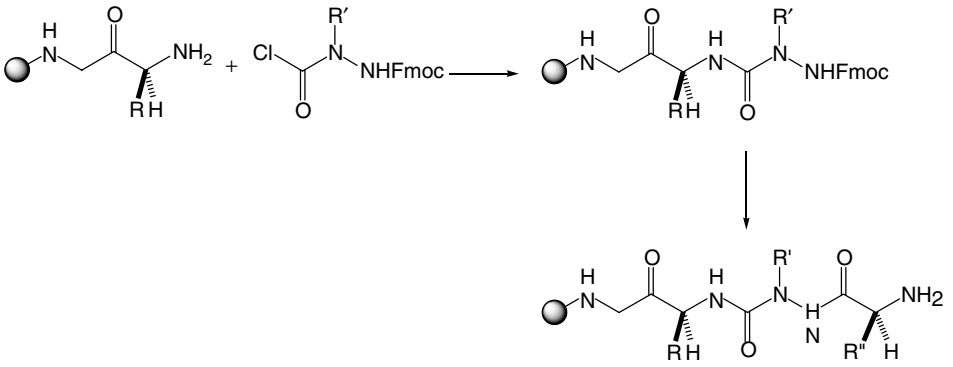
Scheme 2



Scheme 3



Scheme 4



Scheme 5

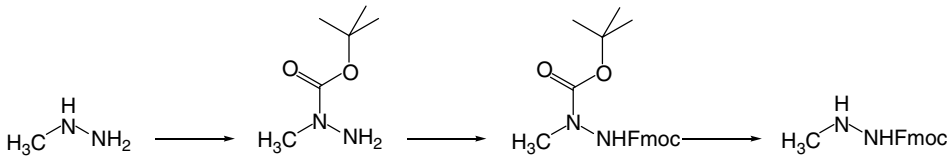
done by preparing the Boc-hydrazides of suitable aldehydes or ketones and then reducing them by catalytic hydrogenation (Scheme 4).

In 2001, Hart and Beeson in a newer example of compounds introduced important modifications allowing the use of solid-phase Fmoc methodology on Rink amide resin (Scheme 5).

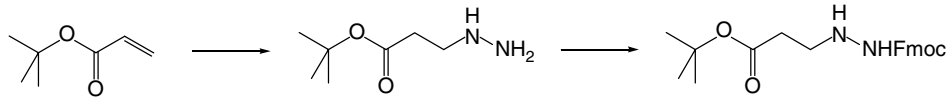
A large series of compounds of this class, based on the sequence of the antigenic hen ovalbumin pentadecapeptide Gln-Ala-Val-His-Ala-Ala-His-Ala-Glu-Ile-Asn-Glu-Ala-Gly-Arg by replacing one amino acid at a time by azaglycine, azaalanine, or azaglutamic acid, bound detectably to the major histocompatibility complex. Some of them, for example, Gln-Ala-Val-His-Ala-Ala-His-Ala-Glu-Ile-Gly^{a}-Glu-Ala-Gly-Arg (where the superscript^{a} indicates an azaamino acid), were as potent as activators of T cells as the native peptide.

The azaalanine monomer was built starting from methylhydrazine (Scheme 6). Synthesis of the azaglutamic acid started from *tert*-butyl acrylate (Scheme 7).

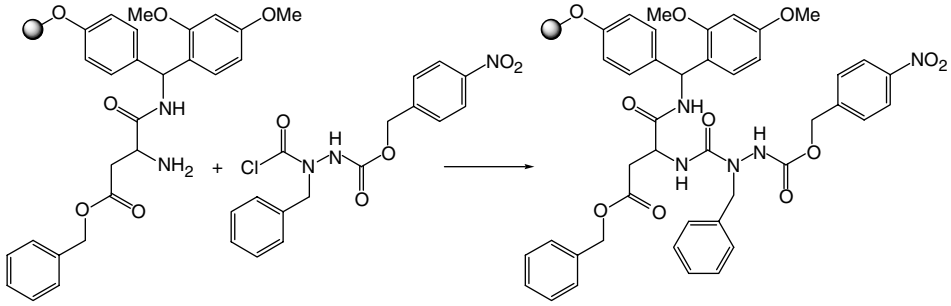
A recent patent describes an apparently general method for the preparation of azapeptides or azatides that, like Hart and Beeson's procedure in 2001 but unlike earlier methods, is amenable in theory to automated synthesis by modification of existing protocols. An important advantage



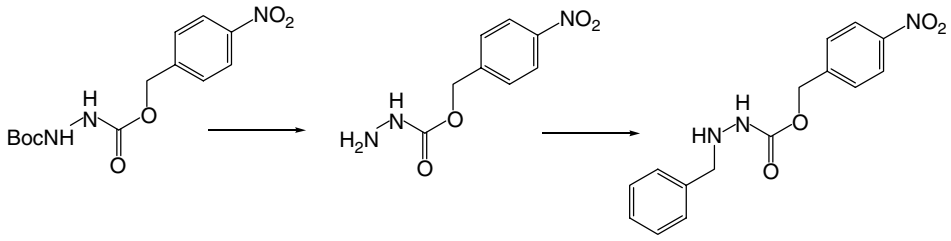
Scheme 6



Scheme 7

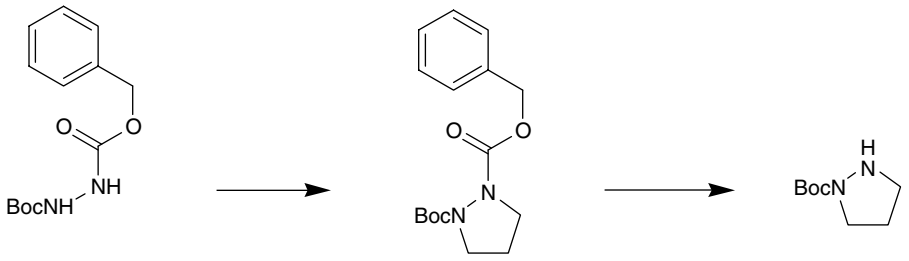


Scheme 8



Scheme 9

of this over earlier methods is that it uses the same basic reaction sequence as the Merrifield synthetic strategy. This involves the reaction of an azaamino acid building block, protected with a group such as *p*-nitrobenzyl, with a carbonyl-releasing agent such as phosgene in the presence of base to afford a protected, activated carbonyl azaamino acid. This crude product is subsequently allowed to react with a resin-bound amino acid, peptide, or amino acid or peptide azaanalog (Scheme 8). Subsequent cleavage of the protecting group, for example, with $SnCl_2$, releases the freshly synthesized, resin-bound azapeptide. This methodology requires the synthesis of azaamino acid building blocks, which can usually be achieved in three steps by reaction



Scheme 10

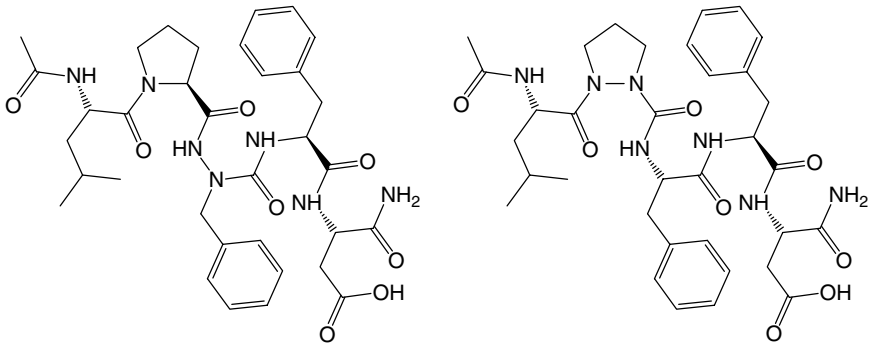


Fig. 1 Two azapeptide analogs of Ac-Leu-Pro-Phe-Phe-AspNH_2.

of *t*-butyl carbazate with *p*-nitrobenzyl chloroformate, selective removal of the *t*-butyloxycarbonyl group, and alkylation of the primary amino group (Scheme 9).

A slightly different challenge is posed by the azaproline moiety, which was synthesized according to the sequence shown in Scheme 10. In this particular case, the t-butyloxycarbonyl derivative was used directly in the chlorocarbonylation and coupling steps. This methodology was used to synthesize azapeptides such as Ac-Leu-Pro-Phe[a]-Phe-AspNH_2 and Ac-Leu-Pro[a]-Phe-Phe-AspNH_2 (Fig. 1).

3 β-, γ-, δ-, ε-, and Related Peptides

β-,γ-, δ- and ε-peptides are oligomers of β-, γ-, δ- or ε-amino acids (Fig. 2). Depending upon their backbone substitution, they may be classified as β^2-, $\beta^{2,2}$-, β^3-, and so on (depicted are only β^2-, γ^2-, δ^2- and ε^2- peptides). Although sugar amino acids are not covered in this chapter, they may also be viewed as building blocks for conformationally restricted β-, γ-, δ-, and ε-peptides, for example, Fig. 3. These compounds have been reviewed as recently as 2002 by Gruner et al.

Another recent review, concentrating on the structure of β-peptides, but also briefly reviewing their biological properties, is that of Cheng et al. in 2001. Another review by Lelais and Seebach in 2004 with an update of the subject almost to the present day would render any other attempt repetitious at this time.

On several occasions, γ-peptides have been reported to adopt hydrogen bond–stabilized helical conformations, but in

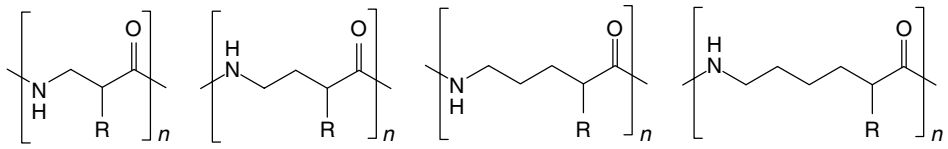

Fig. 2 General structures of β^2-, γ^2-, δ^2- and ε^2- peptides.

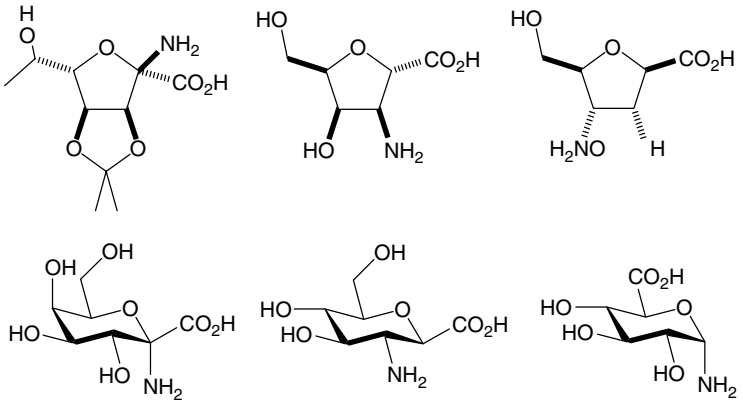

Fig. 3 Examples of sugar amino acid building blocks.

oligomers of γ-amino acid residues, a sheet secondary structure is preferred. Nowick and Brower in 2003 and Zhao et al. in 2004 have constructed bulky N^{α}-acylornithine-derived δ-peptides that adopt well-defined folded conformations, unlike earlier, presumably more flexible examples. The synthesis of these compounds usually adheres to standard peptide synthetic methodology.

4 Aminooxy Peptides

α-,β- and γ-aminooxypeptides are analogs of β-, γ- or δ-peptides in which the β-, γ- or δ-carbon is replaced by an oxygen atom (Fig. 4). The unusual conformational properties of peptides containing a single α-aminooxy acid residue were first predicted and observed by Yang et al. in 1996. A recent important development in this field was the first solid-phase synthesis of oligomeric α-aminooxy peptides. This was based on the stepwise extension of a resin-bound α-phthalimidoxy acid (Scheme 11). The same group has introduced 2-oxanipecotic acid as a cyclic α-aminooxy acid for conformational studies, for example, Fig. 5. The synthesis of phthaloyl δ-aminooxy acids, the building blocks of chiral δ-aminooxy peptides, has been reviewed and improved upon by Shin et al. in 2000.

Chiral β^3-aminooxy peptides are a recent development. They have been obtained in a straightforward manner by coupling of phthalimidoxy acids with the free amino groups of their partners, under similar conditions to those used previously by the same authors. The chiral β^3-aminooxy amino acid building blocks were synthesized from chiral α-aminooxy

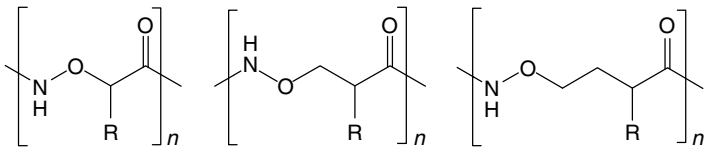

Fig. 4 General structures of α-, β- and γ- aminooxypeptides.

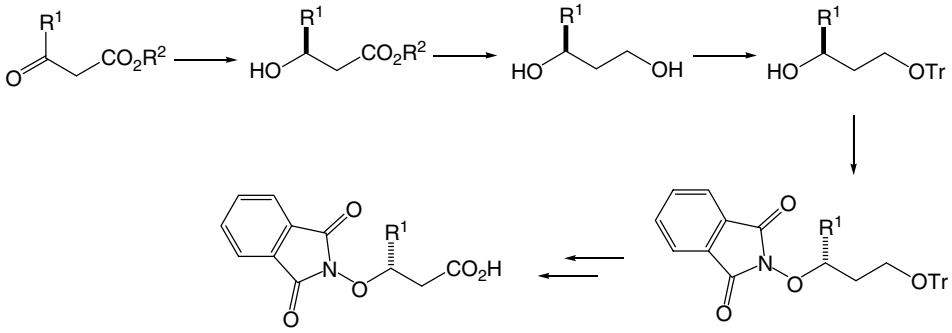
acids by Arndt-Eistert homologation (Pg = protecting group) (Scheme 12) or, preferably, by enantioselective reduction of β-keto esters using either baker's yeast or chiral Ru(II) complexes, followed by reduction of the ester group and amination of the secondary alcohol (Scheme 13).

γ^4-Aminooxy peptides have also been synthesized very recently and have been shown to adopt unique helical conformations, different from those of homochiral oligomers of α- and β-aminooxy acids (Fig. 6). Experimental details of their syntheses have not yet been published.



Scheme 13

5 Oligocarbamate and Oligourea Peptidomimetics

Oligocarbamate peptide mimetics were first synthesized as a library by Cho et al. in 1993, using methodology described for the preparation of peptide libraries. Their general structure may be depicted as shown in Fig. 7. The first successful attempts to prepare oligourea peptidomimetics (Fig. 8) using solid-phase technology were published in detail by Burgess et al. in 1997 and Kim et al. in 1996. The carbamate or urea amino acid analogs are generally represented by the usual three- or one-letter amino acid notations with the superscripts c or u, respectively.

The earlier methods were based on phthalimido-protected isocyanates and azido 4-nitrophenyl carbamates as building blocks, which diverge considerably from the standard methodologies using, for example, Fmoc-protected amino acids or amino acid analogs, such as described by Chan and White in 2000. More recent detailed protocols for the solid-phase synthesis of oligourea peptidomimetics and their building blocks using Fmoc protection under conditions mimicking those used in automated peptide synthesis are given in Boeijen et al. (2001). The general procedure is based on the extension of a Rink amide resin-linked starter by successive addition of Fmoc and p-nitrophenyl-protected urea monomers with intermediate capping and deprotection steps (Scheme 14). Most of the monomers were synthesized from Fmoc-protected amino acids by successive conversion to the corresponding alcohols, azides,

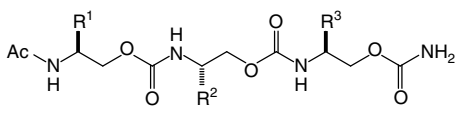


Fig. 7 An oligocarbamate peptide mimetic.

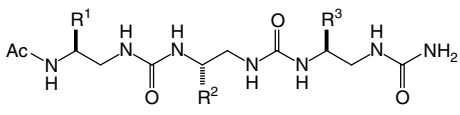

Fig. 8 An oligourea peptide mimetic.

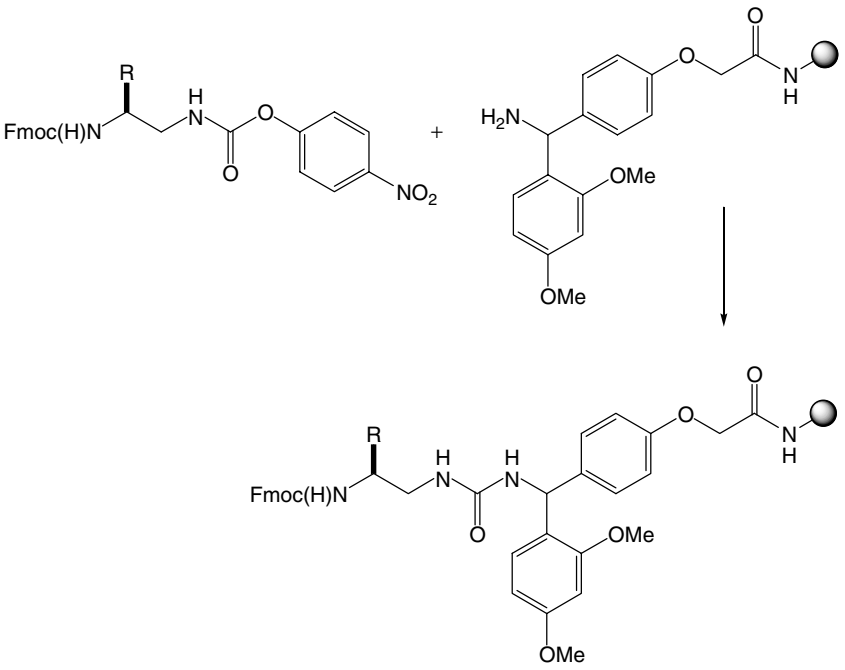
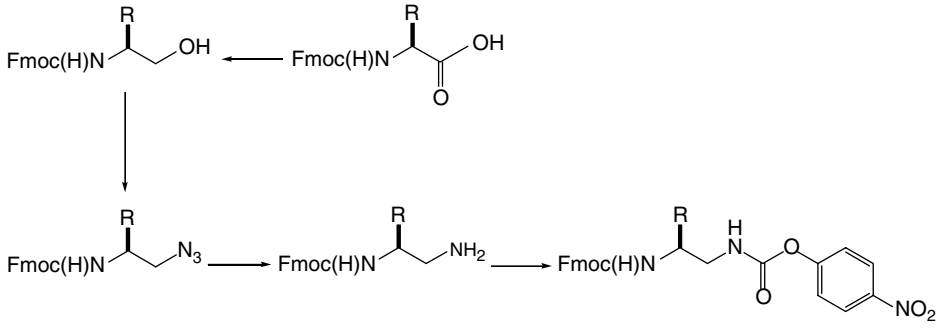


Scheme 14



Scheme 15

and amines, which were finally derivatized to the p-nitrophenyl carbamates (Scheme 15). The Fmoc-protected glycine urea monomer, however, was prepared from Boc-ethylenediamine. This methodology was used to synthesize Ac-Gly^{u}-Gly^{u}-Phe^{u}-Leu^{u}-NH_2 and a couple of neurotensin analogs.

6 Peptoids

Peptoids are N-alkylglycine oligomers, that is, peptide mimetics in which side chains are bound to the amide nitrogen atom rather than to the α-carbon atom (Fig. 9). Peptoid synthesis based on commercially

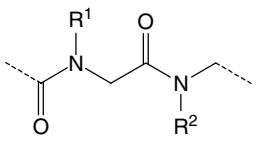


Fig. 9 A dipeptoid moiety.

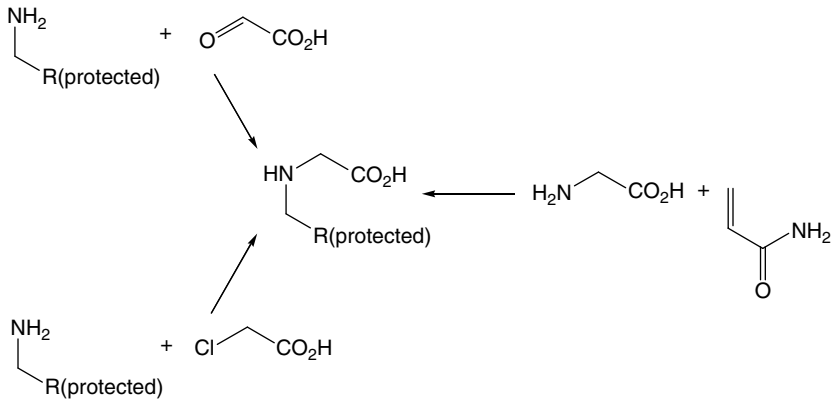

Scheme 16

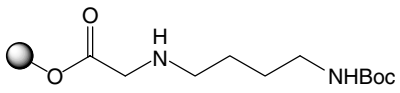

Fig. 10 A resin-bound peptoid residue.

available primary amines is eminently amenable to the preparation of very large libraries using combinatorial approaches. Earlier work in this direction, pioneered by Zuckermann's group has been reviewed by Figliozzi et al. in 1996. A limitation of such processes has been the long reaction time (of up to several hours) required for the coupling of each residue. However, it has been shown in 2002, by Olivos et al. that the solid-phase synthesis of peptoids can be successfully accelerated under microwave irradiation, achieving reaction times of less than one minute. The basic strategy is the approach described by Simon et al. in 1992), which uses standard solid-phase synthesis techniques. The monomers are prepared by different methods from appropriate primary amines (Scheme 16).

Shankaramma et al. in 2003 synthesized tetradecapeptide-peptoid macrocycles containing a single N-substituted glycine residue, allowing a β-hairpin conformation induced by two successive proline residues to be maintained, stabilized here by the array of intramolecular hydrogen bonds between carbonyl and NH groups. The synthesis of the linear precursor was carried out on 2-chlorotrityl chloride-polystyrene resin using Fmoc chemistry, initially binding bromoacetic acid to the resin and then replacing the bromine with a 4-Boc-aminobutylamino group to create the single peptoid residue as a starting point (Fig. 10). This precursor was then

released from the resin, cyclized and deprotected to afford the final product.

7 Variations on the Peptoid Theme

Several new variations on the peptoid theme have been synthesized. One of the earliest is the ureapeptoid structure built by Kruijtzer et al. in 1997 and by Wilson and Nowick in 1998 (Fig. 11). Ureapeptoids can be prepared from Boc-protected *N*-1-substituted ethylenediamines, by conversion to the corresponding isocyanates and condensation of the latter with sarcosine methyl ester (Scheme 17). Subsequent removal of the Boc protective group and condensation with an appropriate *p*-nitrophenyl carbamate allowed extension of the chain to a ureapeptoid trimer.

A more efficient method starts from Boc-ethylenediamine or oligomers containing this moiety, by chain extension with *N*-(2-nitrobenzenesulfonyl)-2-imidazolidinone containing the Ns protective group of Fukuyama et al., 1995 followed by N-alkylation and deprotection (Scheme 18).

Retropeptoids, for example, Fig. 12, are peptidomimetics in which the substituted nitrogen atom of the peptoid N-substituted glycine is moved up one position to replace the α-carbon atom as described

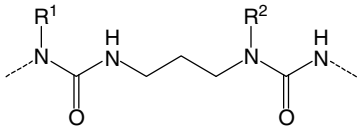

Fig. 11 A ureapeptoid moiety.

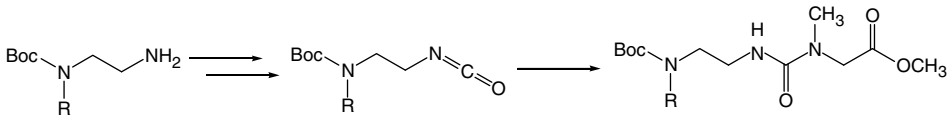
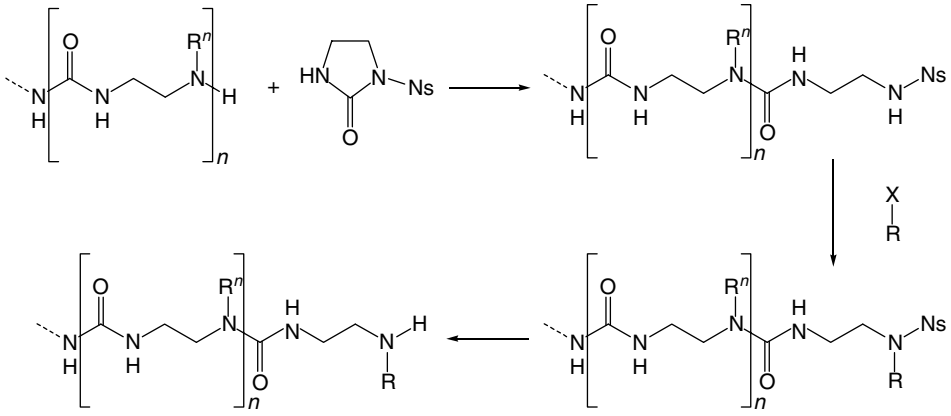


Scheme 17



Scheme 18

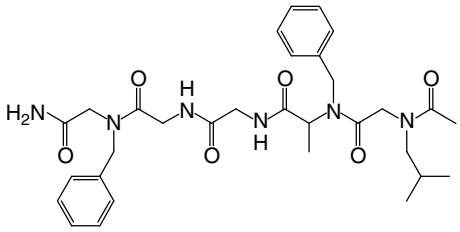


Fig. 12 A retropeptide.

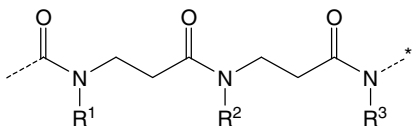

Fig. 13 A β-peptoid moiety.

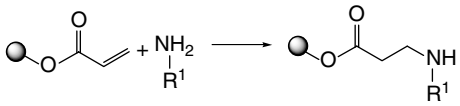
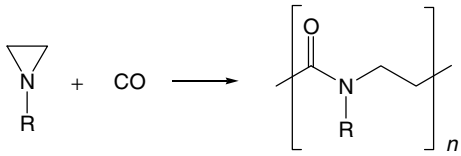
Scheme 19



Scheme 20



by Kruijtzer et al. in 1998. β-Peptoids (Fig. 13) are N-substituted oligomers of β-aminopropionic acid. This type of oligomer had been prepared previously by coupling of N-substituted β-amino acids as explained by Seebach et al. in 1996 using standard peptide methodology, and shown to be stable toward pepsin. The Seebach approach suffers from the limitation that it requires a collection of β-amino acid monomers as building blocks. Hamper et al. in 1998 devised a solid-phase strategy, based on the Michael addition of primary amines to an acrylic acid residue bound to Wang resin by treatment with acryloyl chloride (Scheme 19). Successive couplings with acryloyl chloride followed by the addition of primary amines and finally cleavage from the resin led to the synthesis of several di-β-peptoids, as well as trimeric *N*-benzyl-β-aminopropionic acid, the latter in 67% overall yield.

Poly-β-peptoids are oligomers of a single N-substituted β-aminopropionic acid residue. Approaches to these structures by copolymerization of CO and imines were explored initially by Kacker et al. in 1998 and by Dghaym et al. also in 1998, and have been developed into a successful catalytic method by the group of Jia in 2002 and Darensbourg in 2004. This involves the alternating copolymerization of carbon monoxide and an N-alkylaziridine using a cobalt carbonyl catalyst (Scheme 20).

Hydrazinoazapeptoids are based on the hydrazinopeptide concept (Fig. 14). The synthesis of hydrazinoazapeptoids (as hybrids with a hydrazinopeptide moiety)

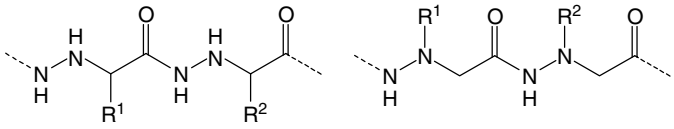


Fig. 14 A hydrazinopeptide and a hydrazinopeptoid moieties.

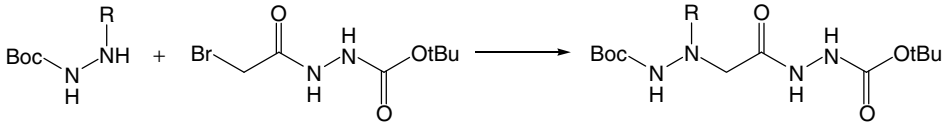
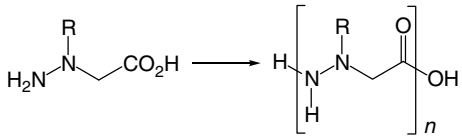
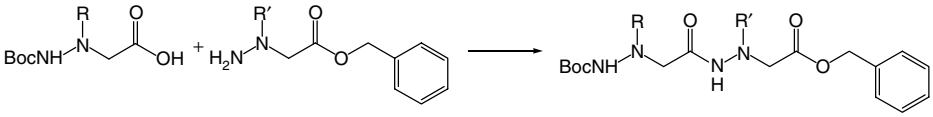


Scheme 21

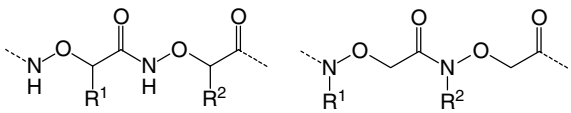
Scheme 22





Scheme 23

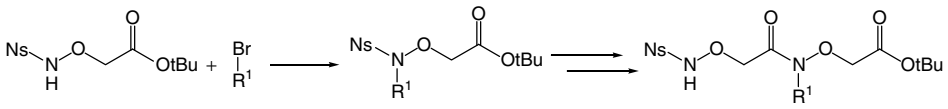
Fig. 15 An aminooxypeptide and an aminooxypeptoid moieties.



has been carried out in solution, using the submonomer approach, which implies alkylation of one of the nitrogen atoms of a monosubstituted alkyl or arylalkylhydrazine with a bromoacetyl residue on the growing oligomer, requiring the use of protected hydrazine derivatives to insure alkylation at the desired position (Scheme 21).

Aza-β^3-peptides are oligomers of N^{α}-substituted hydrazinoacetic acid, and may also be regarded as aza analogs of β^3-amino acids (Scheme 22). The monomers can be synthesized as N^{β}-Boc-protected benzyl or methyl esters, and monomers, dimers, and oligomers all coupled very efficiently under DCC/DMAP (dicyclohexylcarbodiimide/dimethylaminopyridine) activation, followed by deprotection and elongation steps as required (Scheme 23).

Aminooxypeptoids, based on the aminooxypeptide concept, can be envisioned as *N*-alkyl- or arylalkylhydroxylamine derivatives (Fig. 15). The synthesis of aminooxypeptoids has also been accomplished using the submonomer approach



Scheme 24

(Ns represents *o*-nitrobenzenesulfonyl), but unacceptably low yields were obtained (Scheme 24). Stepwise assembly of the N-alkylated monomers in either the N to C or the C to N direction proved to be more satisfactory, although yields were still low when bulky side chains were present at the terminal positions of the deprotected monomers.

8 Proline Substitutes

The cyclic structure of proline and the similar stabilities of cis- and trans-peptide bonds involving its secondary amine nitrogen, separated by a relatively low potential energy barrier, are features that explain the unique roles of this amino acid. As similar properties are found in other $N^{\alpha}-C^{\alpha}$-cyclized amino acids, a number of proline mimics with different ring sizes have been synthesized and incorporated into peptides. These modifications are discussed in the Goodman and Ro review (1995), as well as others in which an additional heteroatom and/or a conformationally stabilizing feature such as a double bond, a bicyclic system, or a *gem*-dimethyl substitution is included in the proline ring. A number of proline substitutes have been biologically characterized (see Sect. 9).

9 Biological Activity and Therapeutic Hints

Although theoretically considered as promising fields to develop innovative therapies for a number of relevant human diseases, the biological characterization of most of the peptide mimetics described here has not been the subject of too much research, as compared with the abundant literature regarding synthetic aspects. Regarding endogenous peptides, these were used rather intuitively. Some classical examples are insulin, human growth hormone, interferons, or erythropoietin. Peptidase inhibition, as illustrated by angiotensin-converting enzyme (ACE) inhibitors, also offers enormous therapeutic opportunities, and the many successful ACE inhibitors currently available may be viewed broadly as mimics of the peptide substrate. Moreover, peptide processing is a crucial step in viral replication, and protease inhibition has become a fundamental aspect of HIV antiretroviral therapy. Increasing knowledge of the roles of peptidases is continually suggesting novel approaches to the treatment of disease. Therefore, the design and synthesis of substrate or transition state analogs to inhibit these enzymes is another fertile field of research.

While these molecules have found some clinical use, the drug potential of many others remains unrealized. One reason for this is that peptides are not bioavailable orally, their transport through biological membranes is usually unsatisfactory, and they are rapidly metabolized. Another is that the inherent conformational flexibility of peptides signifies an entropic penalty for them to be able to adopt appropriate conformations to interact with their targets.

Azapeptides such as Ac-Leu-Pro-Phe^{a}-Phe-AspNH_2 and Ac-Leu-Pro^{a}-Phe-Phe-AspNH_2 are effective, proteolytically stable inhibitors of the cytotoxicity of β-amyloid peptide, and are therefore of interest as β-sheet breaking compounds of potential utility in the treatment of diseases such as Alzheimer's, chronic progressive traumatic encephalopathy, and vascular dementia with amyloid angiopathy.

Pure or all-azaaminoacid oligomers or ''azatides'' are azapeptides in which all the α-carbon atoms have been replaced by nitrogen. Although early attempts to synthesize this kind of analog date back as far as the history of (mono)azapeptides, the first successful azatide synthesis appears to be a report by Gante et al. in 1995 on the preparation of an analog of a peptidic renin inhibitor, which, however, does not seem to have been tested. A year later, Han and Janda described the development of general solution-phase procedures for the coupling of Boc-protected azaamino acid monomers and the synthesis of these building blocks. This methodology was exemplified by synthesizing the azatide mimic of Leu-enkephalin. Unfortunately, this product did not compete with Leu-enkephalin for an antibody raised against β-endorphin, the only assay carried out as a test of biological activity. This disappointing result, together with the subsequent discovery that newer azapeptide analogs of the original compound, but with one or more natural amino acid residues, also lacked this activity, may explain why this avenue of research does not seem to have been followed more extensively.

On the basis of the sequence of the RNA-binding domain of HIV-1 Tat protein, ^{48}Gly-Arg-Lys-Lys-Arg-Arg-Gln-Arg-Arg-Arg^{57}, Tamilarasu et al. in 2001 synthesized an oligocarbamate (Phe-Gly^{c}-Arg^{c}-Lys^{c}-Lys^{c}-Arg^{c}-Arg^{c}-Gln^{c}-Arg^{c}-Arg^{c}-Arg^{c}) and an oligourea (Gly^{u}-Arg^{u}-Lys^{u}-Lys^{u}-Arg^{u}-Arg^{u}-Gln^{u}-Arg^{u}-Arg^{u}-Arg^{u}-Tyr) analog, which inhibited transcriptional activation by Tat protein in human cells with IC_{50} values of 1 and 0.5 μM, respectively.

The pharmacological activity of peptoids designed as analogs of peptides with recognized bioactivity has often been disappointing. Nevertheless, some peptoid structures lacking any obvious fit to a target exhibit interesting activities. Thus, a combinatorial library of peptoid trimers yielded several new compounds (with a large, lipophilic, nonpeptidomimetic, also antibacterial dehydroabietylamine moiety and unnatural amino acid–like residues) exhibiting activity against both gram-negative and gram-positive bacteria, including some resistant strains to all known antibiotics. The MIC (minimal inhibitory concentration) values were as low as 5 μM in some cases. One of the analogs fully protected *Staphylococcus aureus*-infected mice at 10 and 30 mg kg^{-1} (Fig. 16).

It should be pointed out that dehydroabietylamine itself is no more than an order of magnitude less potent *in vitro* than the most effective peptoid hybrid of this series. Nevertheless, it is inactive in the infection

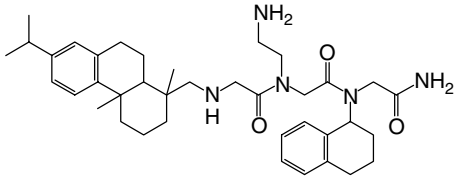


Fig. 16 A dehydroabietylaminopeptoid.

model, suggesting that the pharmacokinetics for some peptoids is more favorable. The authors suggest that, because of their broad spectrum of antibacterial activity, their lack of structural specificity, and β-galactosidase and propidium iodide leakage, these substances act on the bacterial cell membrane. Although the more thoroughly studied compound depicted above had some hemolytic activity, this appeared at concentrations greater than the MIC for staphylococci. The screen that led to these compounds showed that dehydroabietylamine, at any of the three positions, although preferably at the N-terminal location, was a frequent (but neither necessary nor sufficient) component of the active analogs. The extension of the antibacterial spectrum to gram-positive organisms seems to be related to the presence of a basic residue (such as the aminoethyl group mentioned earlier) at the intermediate position.

Quite recently, a conjugate of ethylenediaminetetraacetic acid (EDTA) with two 5-aminosalicylic acid (5-ASA) methyl ester moieties (EBAME), was described (Fig. 17). This compound can be viewed as a peptoid in which two glycine conjugates are joined through their α-amino acid nitrogen atoms, combining the anti-inflammatory activities of 5-ASA, with the redox-active metal chelating activity of acid (EDTA), suppressing the gastric irritation mediated by 5-ASA, removing potentially harmful transition metal ions and mimicking superoxide dismutase (SOD) when complexed with Cu^{2+} ions. EBAME was shown to bind to Cu^{2+} in a 1 : 1 ratio, but the superoxide-destroying activity of this complex was rather low. With Mn^{2+}, however, a very satisfactory SOD-like activity was demonstrated. The authors claim that EBAME has potential as a dual-function anti-inflammatory agent with reduced gastric irritant potential.

A couple of macrocyclic peptide–peptoid hybrids, mentioned in Sect. 6, has also quite recently been shown to have antibiotic activity against gram-positive and – negative bacteria, with low hemolytic activity against erythrocytes, one of the major drawbacks of earlier members of this class (Fig. 18). The replacement of an arginine group N-substituted glycine residue present in a previously synthesized purely peptidic prototype by an *N*-4-aminobutyl-substituted glycine residue led to a slightly

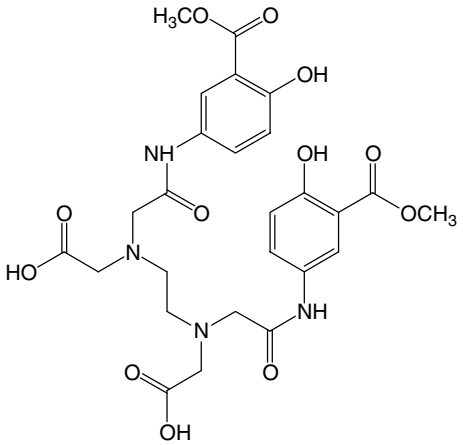

Fig. 17
Ethylenediaminetetraaceptic acid bis-(5-aminosalicylic acid methyl ester) (EBAME).

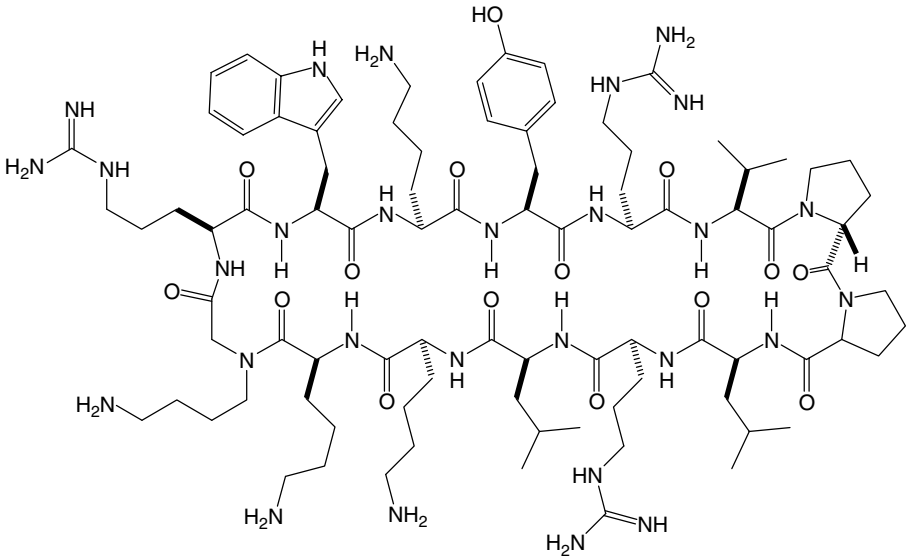

Fig. 18 A macrocyclic peptide–peptoid hybrid.

improved antibiotic potency (MIC between 4 and 64 μg mL^{-1}) and reduced hemolytic activity (0.5% at 100 μg mL^{-1}), while preserving the β-hairpin conformation believed to be important for this biological activity.

When α-chiral, bulky side chains are repeated along a peptoid backbone, stable helical structures arise in spite of the lack of potentially hydrogen-bonding NH groups. The same structural concept has been applied to the design and synthesis of a mimic of lung surfactant protein C, containing 22 N-substituted glycine residues. This product successfully reproduces several desirable characteristics such as the ability to adsorb rapidly to an air–water interface, to reduce and control surface tension and to respread quickly upon surface expansion (Fig. 19).

Several helical, cationic, amphipathic peptoids designed as mimics of the natural magainins have also shown antibacterial activity, for example, Fig. 20.

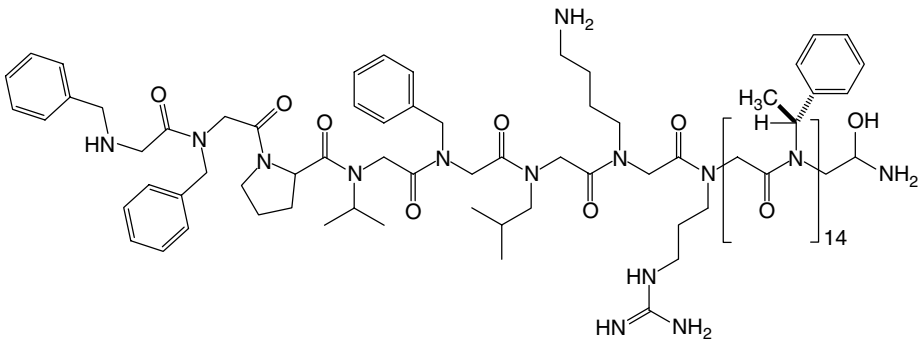

Fig. 19 A peptoid mimic of lung surfactant protein C.

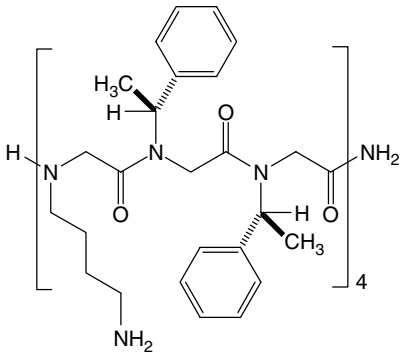

Fig. 20 A peptoid magainin mimic.

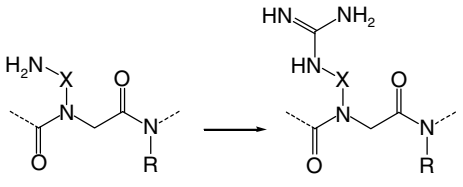
These oligomers were prepared from peptoid polyamines, synthesized sequentially on Rink amide resin, which were then guanidinylated using pyrazole 1-carboxamidine (Scheme 25).

The retropeptide Leu-enkephalin amide mimic depicted earlier (Fig. 12) appears not to have been subjected to biological testing. The more complex substance P peptoid and retropeptoid analogs, however, are reported to be *in vitro* agonists in the above-mentioned article, although this observation does not seem to have been followed up by a more thorough pharmacological study. Rather surprisingly, the high resistance of the peptoid analog to degradation by pepsin is mentioned as evidence that the retropeptoid is similarly stable.

Some hydrazinoazapeptoids designed as possible proteasome inhibitors, based on the Ac-Leu-Leu-Norleucinal template, exhibit antiproliferative activity in L1210 cells, for example, Fig. 21, but their potency is weak compared to that of the structurally unrelated, proven proteasome inhibitor bortemozib.

A recent successful example is the synthesis of a potent ($K_i = 1.5$ nM), specific human proline endopeptidase inhibitor



Scheme 25

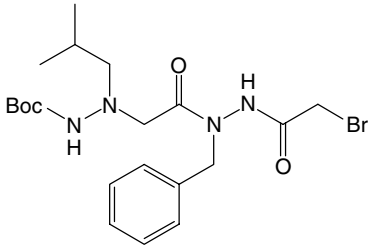


Fig. 21

that was viewed as a probe of the possible role of this enzyme in the production of β-amyloid peptide, a hallmark of Alzheimer's disease (Fig. 22).

A newer development is the replacement of a proline residue by a cyclopent-2-ene-1,2-dicarboxylic acid moiety. Applying this concept, these authors synthesized and evaluated a series of thrombin inhibitors related to inogatran and melagatran (in which the pyrrolidine ring of a proline residue is replaced by a piperidine or an azetidine ring, respectively), some of them with submicromolar IC_{50} values, which, however, are still somewhat unsatisfactory when compared with the 22.4 and 4.7 nM IC_{50} values of the reference compounds. Their most potent example ($IC_{50} = 0.87\ \mu M$) is shown in Fig. 23. For the sake of comparison, the analog lacking the N-ethoxy group has $IC_{50} = 1.51\ \mu M$. Although the (2R)-cyclopent-2-ene-1,2-dicarboxylic acid moiety generally afforded more potent compounds, its replacement by trans-(1S,2S)-cyclopentane-1,2-dicarboxylic acid in the latter example results in slightly enhanced activity ($IC_{50} = 1.32\ \mu M$). This structural modification has been incorporated much more successfully into inhibitors of prolyl oligopeptidase, a serine peptidase that preferentially catalyzes the hydrolysis of peptide bonds at the carboxyl side of proline residues. Thus, the following analog has a 0.3 nM IC_{50}, while the corresponding value for the reference compound with a proline residue in the central position is 0.2 nM (Fig. 24).

Recents efforts in this direction are those of Han et al. in 1999, Avenoza et al. in 2002, and Jenkins et al. in 2004. The former authors used 7-azabicyclo[2.2.1]heptane-1-carboxylic acid as a proline replacement in a boroarginine thrombin inhibitor, and as an inducer of a β-turn in the dipeptides Ser-Pro and Pro-Ser for conformational studies (Fig. 25).

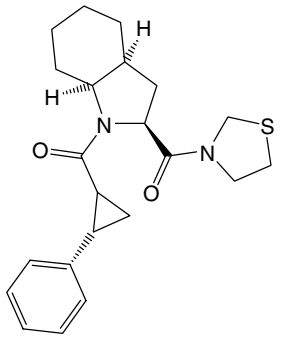

Fig. 22

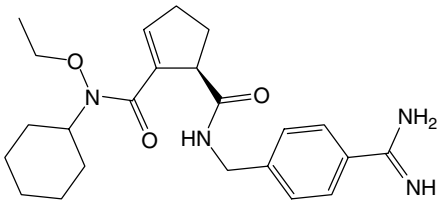

Fig. 23

Fig. 24

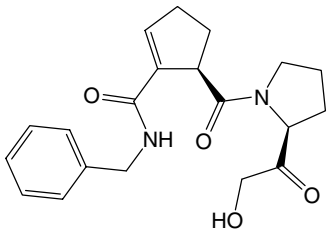

Fig. 25

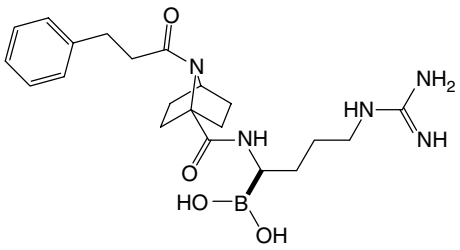

This substance, synthesized from 7-Boc-1-carboxy-7-azabicyclo[2.2.1]heptane t-butyl ester, inhibited thrombin with K_i = 2.9 nM, which compares reasonably well with the parent proline compound (K_i = 0.10 nM) suggesting that this replacement mimics the active conformation in Han et al. in 1999.

The more recent paper analyzed the implications of this replacement, with electronegative (HO or F) substituents at C-4, for the conformation of collagen. Jenkins et al. in 2004 concluded that the bridge abolishes the effect of the electronegative substituents on the proline ring on the trans/cis ratio of the peptide bonds, previously observed by the same group with unbridged, electronegatively substituted proline residues.

The unique features of peptide-inspired derivatives pose many synthetic challenges that must still be met. Certain structural aspects, such as the tendency of different peptidomimetic scaffolds to adopt stable conformations in solution, are currently a very active field of research that is also a stimulus for the development of novel synthetic methodologies. In view of the extremely varied therapeutic potential of peptide mimetics, the development of reliable therapies based on these compounds will require further expansion of the broad spectrum of synthetic methods available in order to overcome the current practical limitations of these very versatile moieties, without altering their essential chemical nature. This frontier in the field of peptide mimetics will foreseeably be a major area of research in the coming years.

Amino Acids
The building blocks of peptides (as well as polypeptides and proteins) are amino acids. Chemically, an amino acid consists of a central carbon (termed *α-carbon* or C-α) to which are attached an amino (NH_2) group, a carboxyl (CO_2H) group, a side chain (generically referred to as an *R group*), and a hydrogen (H) atom. Amino acids differ in terms of their R group, and the three-dimensional chemical structure (or configuration) of amino acids also may be differentiated at the central α-carbon, except where R is hydrogen. With the exception of glycine, the configuration of the 20 naturally occurring amino acids is designated as L (unless specified otherwise).

First and Second Messengers

Peptide hormones are considered to be first messengers because they initiate a cellular/tissue response by interacting with cell surface receptors (ligand-specific binding molecules). Peptide (exemplifying a class of ligand) binding then leads to an amplified cascade of signal transduction events that increase or decrease production of specific intracellular (second) messengers. Second messengers include cyclic 3′,5′-adenosine monophosphate (cAMP), cyclic 3′,5′-guanosine monophosphate (cGMP), diacylglycerol (DAG), inositol triphosphate (IP3), and calcium ion (Ca^{2+}). Receptor-coupled effector enzymes or transport proteins (e.g. adenylate or guanylate cyclase, phospholipase, calcium channels) regulate intracellular levels of such second messengers.

Peptidomimetics and Nonpeptides

More complete synthetic tailoring of a peptide to yield analogs having essentially no naturally occurring amino acids or dipeptide substructure became popularized during the past two decades on the basis of the premise that such compounds might be better suited for drug development, being low in molecular mass, metabolically stable, and bioavailable by oral administration. Such radically modified peptides are generically referred to as *peptidomimetics* (including peptoids and pseudopeptides), and such compounds vary significantly in terms of the nature of the chemical template and design strategy used. ''Nonpeptide'' is used here to generically refer to molecules originally derived from screening of natural product sources or chemical files that competitively displace the natural peptide (or synthetic peptide analog) from the native receptor/enzyme target. In contrast to peptidomimetics, which are designed on the basis of chemical information of a peptide lead or its target receptor/enzyme active site, the discovery of nonpeptides from screening strategies may yield compounds that have no obvious chemical similarity to the native peptide (or synthetic peptide analog).

Primary Structure

The primary structure of a peptide is defined as the linear ordered linkage of constituent amino acids from the N terminus to the C terminus. ''Primary sequence,'' although often used, represents incorrect terminology.

Recombinant Peptides

These include naturally occurring peptides as well as analogs containing naturally occurring amino acids. Such peptides may be prepared by biosynthetic methods based on overexpression of a cloned gene to yield high levels of the desired peptide (or precursor) in a host organism or cell line from which the peptide can subsequently be processed and/or purified to homogeneity.

Secondary Structure (Conformation)

The three-dimensional properties of peptides (as well as polypeptides and proteins) are determined by the individual compound's amino acid sequence, the spatial orientation of both its backbone and side chains, and its characteristic specific intramolecular hydrogen-bonding interactions. Peptide conformations include α-helix, β-sheet, and

β- and γ-turns. Secondary structures may be experimentally determined by spectroscopic and/or crystallographic techniques.

Synthetic Peptides

These peptides, prepared by total chemical synthesis or, in some cases, semisynthesis, provide the opportunity for sophisticated structural modification by incorporation of unusual amino acids, dipeptide replacements or surrogates, and cyclization (involving backbone and/or side-chain linkage), among other types of chemical modifications. Synthetic peptide analogs may be chemically modified in a modest or radical manner with respect to backbone and/or side-chain functionalization. Synthetic alterations of a peptide are exemplified by amide substitution with alkylamide, aminomethylene, ketomethylene, or other nonhydrolyzable isosteres. With the exception of the alkylamide modification, such partial transformation of the backbone amide substructure of a peptide results in analogs generally referred to as *pseudopeptides*. Other typical chemical modifications of synthetic peptides are alterations of the backbone hydrocarbon (CH) substructure by alkylation or stereoinversion.

Peptides are molecules composed of amino acids that are chemically bonded in a specific manner by backbone amide linkage (peptide bond) and, in several instances, by side-chain linkage (e.g. disulfide bond). The discovery and chemical determination of biologically active peptides have become well established over the past few decades. Such work originally needed to overcome two particular challenges: (1) peptides generally exist in very low concentrations, making isolation extremely difficult for early scientists who lacked sophisticated technologies for purification and/or characterization of such molecules as have been more recently developed; and (2) since peptides often consist of a complex molecular framework, early scientists faced major difficulty in accurately determining the structure as well as in proving it by independent chemical synthesis (the latter work, especially, requires highly specific and reversible masking of chemically reactive amine, carboxylate, and other side-chain functionalities of each constituent amino acid).

The rapid development of basic and biomedical research on peptides over the past half-century has been predicated on the premise that peptides are promising molecules for the discovery of new drugs that mimic or block their biological properties. Peptides play key roles in the physiology of all living organisms, as exemplified in humans, where peptides regulate growth, metabolism and development, reproduction, cardiovascular homeostasis, central nervous system (CNS) function, gastrointestinal (GI) function, immune system function, and a plethora of other biological activities.

Over recent years, worldwide attention on peptide chemistry and biological research has been the general theme of international scientific conferences (e.g. biennial symposia of the American, Australian, Chinese, European, and Japanese peptide societies; the Peptide Gordon Conference) and scientific journals dedicated

to such research (e.g. *Journal of Peptide Research, Journal of Peptide Science, Peptide Science (Biopolymers), Peptides, Regulatory Peptides, Neuropeptides*, and *Letters in Peptide Science*). The relative importance of peptide research is evident by the number of Nobel prizes awarded to investigators for their contributions to the science, technology, and/or medicine of these important biomolecules.

Some peptide hormones (e.g. insulin, growth hormone, growth hormone–releasing factor) are being produced on a large scale by recombinant biosynthesis technology to treat specific human afflictions. Human diseases or disorders for which peptide-based drug therapy exists include osteoporosis (calcitonin), diabetes (insulin), prostate cancer and endometriosis (gonadotropin-releasing hormone), acromegaly and ulcers (somatostatin), diuresis and hypertension (vasopressin), hypoglycemia (glucagon), and hypothyroidism (thyrotropin-releasing hormone).

On the basis of the development of the aforementioned naturally occurring or synthetically modified peptide hormones, which are currently marketed as prescription medications, there is hope that such chemically altered peptides (hereinafter referred to as *pseudopeptides, peptidomimetics*, or *peptoids*, according to the type of chemical modification) may also prove useful in therapeutic intervention for still other life-threatening or disabling afflictions, such as immunological dysfunction (e.g. AIDS), cancer, neural dysfunction (e.g. Alzheimer's disease), and cardiovascular dysfunction (e.g. hypertension). Furthermore, the past success of peptide sweeteners (e.g. the dipeptide aspartame) may provide impetus to research and development strategies aimed at the discovery of new applications of peptides.

Peptide Chemistry

1.1
Peptide Structure and Three-dimensional Properties

Peptides are composed of two or more amino acids linked together by a peptide bond (Fig. 1). The number of amino acids determine whether the peptide is referred to as a *dipeptide, tripeptide, tetrapeptide*, and so forth. Of the 20 or so genetically coded amino acids, naturally occurring peptides are generally composed of L-stereoisomers (except for Gly). Peptides, polypeptides, or proteins may be structurally differentiated on the basis of the number of constitutive amino acids (see Table 1). For example, the term "peptide" is frequently used to categorize such compounds ranging from 2 to 20 amino acids. Similarly, "polypeptides" often designate compounds ranging from 20 to 50 amino acids, and "proteins" is used for such molecules of more than 50 amino acids (see Table 2). Although a more precise definition may take into consideration other factors (e.g. three-dimensional chemical complexity or biological function), there still exist a substantial amount of personal preference among experts in this field of research. In this article, the generic term "peptide" is used to designate all such chemical agents or messengers.

The precise linear arrangement, amino $\rightarrow$ carboxy (N $\rightarrow$ C) directionality, of amino acids in a peptide is referred to as

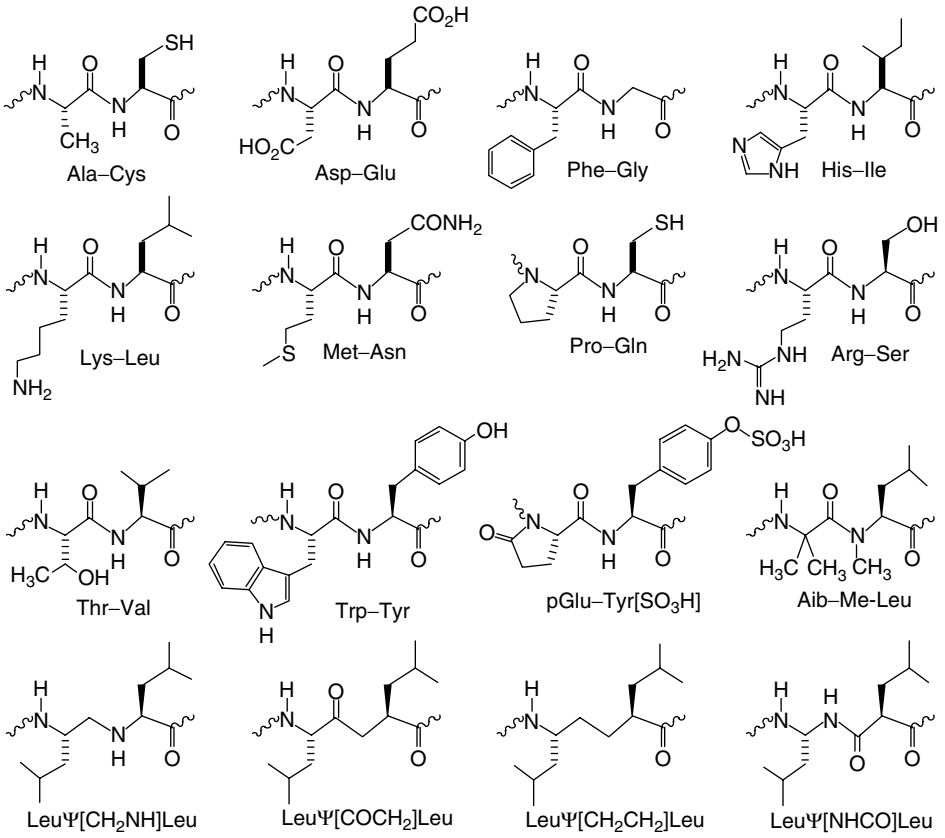

Fig. 1 Chemical structures of dipeptides composed of 20 genetically coded amino acids and some synthetically modified analogs.

its primary structure (Table 3). The three-dimensional folding of the peptide onto itself through covalent (e.g. S−S, disulfide) or noncovalent (e.g. hydrogen and/or ionic) bonding determines the secondary structure of the peptide. Furthermore, the covalent linkage between two or more cysteine residues through disulfide bond formation dictates the transformation of linear peptides to cyclic (or multicyclic) peptides. Such chemically defined restriction of the molecular flexibility of linear peptides does frequently lead toward higher ordered three-dimensional structural complexity and defined spatial arrangement of constitutive amino acid side chains (i.e. tertiary structure). For example, the secondary structure of neuropeptide-Y has been proposed to include a poly-Pro-type helix at the N terminus and an α-helix within its central fragment sequence and a conformationally flexible C terminus. Contributing to such a secondary structure is the tendency of peptides to adopt spatial orientations of both the backbone and side-chain functionalities to bring hydrophobic amino acids (e.g. Trp, Tyr, Phe, Leu, Ile, Val, Met) into proximity to form a hydrophobic surface. Similarly, residues of hydrophilic amino acids (e.g. Lys, Arg,

Glu, Asp, Thr, Ser, Gln, Asn, His) may be distributed within such three-dimensional structures to form a hydrophilic surface that may provide a high degree of solvation by water. In the case of peptides such as growth hormone–releasing factor (GRF) and glucagon, an α-helical-type secondary structure gives rise to amphiphilicity (one side-chain surface being hydrophobic and the other hydrophilic). Furthermore, peptides may be composed of two amino acid chains, or subunits, forming a so-called

[a]Asterisks indicate abbreviations commonly found in the literature.

dimeric structure composed of either homologous or heterologous subunits. The individual subunits may be either covalently (e.g. disulfide) or noncovalently (e.g. ionic or hydrophobic) bonded together. Both interchain and intrachain disulfide bonds may be present within a peptide (e.g. insulin, Table 3). In some cases, such a complex chemical species may be required to establish the biologically active form of a peptide (e.g. nerve growth factor dimer).

The three-dimensional substructure of peptides may be further described in terms of the torsion angles between the backbone amine nitrogen (N-α), backbone carbonyl carbon (C′), backbone hydrocarbon (C-α), and side-chain hydrocarbon functionalization (e.g. C-β, C-γ, C-δ, C-ε of Lys) as depending on the amino acid sequence (Fig. 2). The torsion angle nomenclature is exemplified by the following cases: Ψ, N-α−C-α−C′−N-α; ω, C-α−C′−N-α−C-α; Φ, C′−N-α−C-α−C′; χ_1 N-α−C-α−C-β−X (where X is not hydrogen); χ_2, C-α−C-β−C-γ−X. A Ramachandran plot of Ψ versus Φ for peptides possessing intrinsic secondary structure has further indicated that particular combinations of torsion angles for a helical, reverse-turn, or extended conformation do exist in a predominant fashion. For amide bond torsion angle (ω) the trans geometry is preferred for most dipeptide substructures; when Pro is the C-terminal partner, however, the cis geometry is possible. It is noted that the three-dimensional structural flexibility is directly related to covalent and/or noncovalent bonding interactions within the amino acid sequence of a particular peptide, and synthetic modifications such as N-α alkylation and C-α or C-β alkylation effect significant conformational constraints locally as related to backbone and/or side-chain torsion angles (e.g. conformationally modified Phe analogs, Fig. 2). Finally, it is noted that backbone amide replacements may be defined in terms of a nomenclature system, in which the functional group substitution of the dipeptide substructure is identified as a Ψ[surrogate] (e.g. substitution of the aminomethylene surrogate in Leu-Val would be described as LeuΨ[CH_2NH]Val).

1.2 Peptide Chemical Synthesis and Molecular Diversity

The chemical synthesis of peptides and peptide libraries has advanced tremendously over the past century relative to the pioneering efforts of many scientists (including, in some cases, Nobel laureates) such as George Barany, Max Bergmann, Miklos Bodanszky, Louis Carpino, Theodor Curtius, Emil Fischer, Murray Goodman, Mario Geysen, Richard Houghten, Victor Hruby, Stephen Kent, R. Bruce Merrifield, Stanford Moore, Shumpei Sakakibara, William Stein, James Tam, Claudio Toniolo, Vincent du Vigneaud, and Theodor Wieland. In retrospect, the field of peptide chemistry is enriched with a phenomenal record of achievements involving the solution- and solid-phase synthesis of complex peptides, purification and analytical characterization of peptides, and more recently, the development and implementation of specialized technologies that expedite peptide-based drug discovery in diverse areas of research (e.g. immunology; cardiovascular and neurological physiology). The scope of peptide synthesis pervades both naturally occurring peptides and their analogs, as exemplified by a variety of possible side-chain and/or backbone substitutions that have been developed to exploit conformational modeling hypotheses (local or global

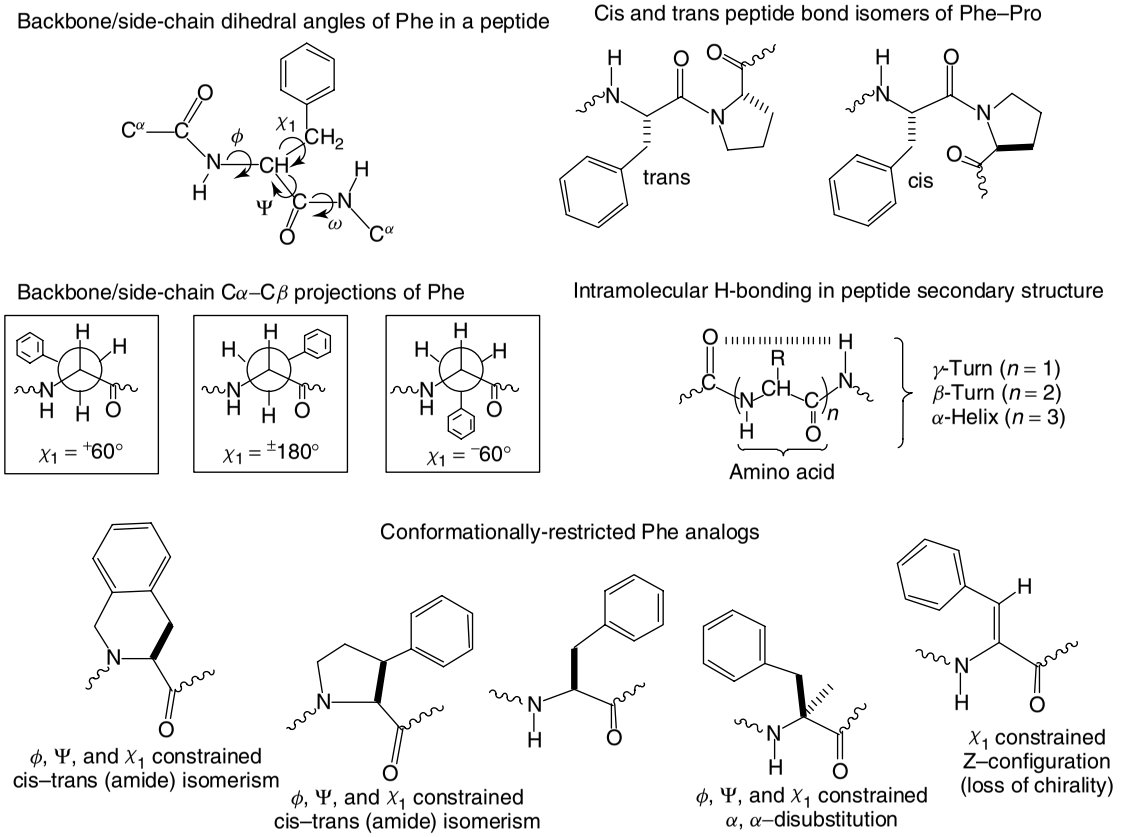

Fig. 2 Three-dimensional structural properties of peptides.

three-dimensional structural constraints), molecular recognition and mechanistic properties at biological targets (receptors, enzymes, antibodies, nucleic acids), and/or metabolism by processing or degrading peptidases. The chemical synthesis of peptides has become a rapidly developed scientific art owing to such factors as automated solid-phase methods, orthogonal protection–cleavage strategies, and a sophisticated database of literature that details possible reagents and potential side reactions to further optimize the task of preparing simple and/or complex peptides. The synthesis of large-sized and/or multicyclic peptides such as interleukin-3, conotoxin, endothelin, transforming growth factor, corticotropin-releasing factor, and calcitonin has been achieved in many research laboratories, and contemporary peptide chemistry methods have been successfully applied to the synthesis of yet more complex macromolecular targets (e.g. HIV protease dimer). Most notably, the chemical synthesis of peptides has expanded to the preparation of combinatorial peptide libraries for which high volume target screening (e.g. receptor binding or enzyme inhibition) is performed to identify compound(s) that possess biological activity. This generally requires the interface of two specialized technologies, namely, synthesis of combinatorial peptide libraries, and their target screening. As opposed to focused analysis of the native peptide with respect to biological activity, such techniques provide tremendous molecular diversity of potential peptide lead compounds to study molecular recognition and mechanistic aspects of peptide interaction with protein (receptors, enzymes), nucleic acid, or carbohydrate targets. Similarly, phage-based peptide libraries have been developed for such applications. The principal advantage of the synthetic peptide or peptidomimetic libraries is the extraordinary molecular diversity of amino acid building blocks that may include unnatural amino acids, pseudodipeptides, and nonpeptide template intermediates.

2
Peptide Biology

2.1
Peptide Biosynthesis and Metabolism

Peptides are biosynthesized on ribosomes, where their specific amino acid sequence is determined (translated) by a specific messenger RNA sequence (codon triplet codes for an amino acid). The nucleotide sequences of the RNA are dictated (transcribed) from specific chromosomal deoxyribonucleotide sequences (DNA genes). Cellular biosynthesis of peptides is believed to proceed very specifically, with error rates of less than 1 in 104 amino acids at a rate of 20 amino acids/ second. The nascent peptides are subsequently released and transported into the cisternae of the rough endoplasmic reticulum and then to the Golgi elements, where they may be posttranslationally modified (e.g. sulfated, glycosylated). Vesicles containing the peptide are pinched off the terminal cisternae of the Golgi apparatus, and then they are targeted to intracellular organelles, the plasma membrane, or are secreted into the extracellular space. In some peptides, the tyrosine residues may be posttranslationally sulfated (Tyr[SO_3H], Fig. 1) as exemplified by the GI peptide hormones cholecystokinin-8 and gastrin. If glutamic acid is present, it may be cyclized into a pyroglutamic acid derivative (<Glu, Fig. 1) as exemplified by thyrotropin-releasing

factor, a hypothalamic peptide. Peptides vary with regard to whether their C terminus is a free carboxylic acid (i.e. $-CO_2H$) or carboxamidated (i.e. $-CONH_2$) and whether the N terminus is a free amine (H_2N-), acetylated (CH_3CONH-), formylated ($HCONH-$), or bearing some other modified amine group (Fig. 1). Some peptides are glycosylated; that is, they are conjugated to one or more carbohydrate groups (e.g. sialic acid). These various examples of posttranslational functionalization are often directly linked to the biological activities of the parent peptides as related to the ''bioactive'' conformation and/or ''message'' sequence of the peptide. Such posttranslational ''tag''î also serve as biomolecular zip codes to target the peptide to a particular cellular compartment. Finally, it is important to note that the amino acid sequence itself may differ to varying degrees among species. This information is useful in determining the evolutionary relatedness between species. Two or more isoforms of a peptide may also exist within an individual species of animal. These isoforms, although chemically similar, may differ either in primary structure length (e.g. cholecystokinin family of CCK-51, CCK-39, CCK-33, CCK-12, and CCK-8 peptides), or in other chemical aspects (e.g. site-specific amino acid substitutions and/or side-chain modification by glycosylation, sulfation, etc.). Gene duplication followed by single or multiple nucleic acid mutations most likely account for such variations in peptide chemical structure and subsequent evolution of various families of peptides (e.g. the neurohypophyseal hormones such as oxytocin and vasopressin).

Some peptides (e.g. oxytocin, vasopressin) require extensive posttranslational processing because they are not coded directly by DNA. Frequently, N- and/or C-terminally extended amino acid sequences are initially biosynthesized. These propeptides may then be packaged within secretory vesicles along with proteolytic enzymes. Both endopeptidases and exopeptidases (Table 4) can contribute to appropriate processing of the inactive precursor peptide to yield the active peptide. Therefore, peptides may be derived indirectly by way of a propeptide, which itself may be derived from a prepropeptide. For example, proopiomelanocortin is a large inactive peptide (MW 28 500) that is cleaved by specific peptidases into several active peptides, including adrenocorticotropin

Tab. 4 Some examples of endopeptidases and exopeptidases.

Aspartyl class	*Cysteinyl class*	*Metallo class*	*Serinyl class*
Pepsin	Cathepsin B	Peptidyl dipeptidase A	Thrombin
Renin	Cathepsin H	Collagenase	Trypsin
Cathepsin D	Cathepsin L	Endopeptidase 24.11	Chymotrypsin A
Cathepsin E	Cathepsin S	Aminopeptidase M	Elastase
HIV protease	Cathepsin M	Carboxypeptidase A	Kallikrein
	Cathepsin N	Stromolysin	Cathepsin A
	Cathepsin T	Gelatinase A	Cathepsin G
	Calpains	Gelatinase B	Cathepsin R
	Papain		Tissue plasminogen activator (TPA)
	Proline endopeptidase		

(ACTH), β-endorphin, α-melanotropin, and β-melanotropin. Some large plasma proteins also serve as propeptides for peptide production. Renin, an enzyme released from the juxtaglomerular cells of the kidneys, acts on a liver-borne substrate protein (angiotensinogen) to convert it to the decapeptide angiotensin I, which is then processed by another enzyme to yield the active peptide hormone angiotensin II. Other precursor plasma proteins, the kininogens, are similarly converted by specific serine proteases (kallikreins) to kinins, such as bradykinin, which is an important peptide hormone in regulating blood flow in certain vascular beds. Bradykinin and angiotensin II are examples of peptide hormones that are released from liver cells as larger propeptides to be converted into active hormonal peptides within the blood. In contrast, peptidases may also inactivate peptides by splitting the molecules at specific internal peptide bonds. Exopeptidases, both carboxypeptidases and aminopeptidases, cleave off the C-terminal or N-terminal amino acids, respectively. Some peptides may be inactivated by simple deamidation at the C-terminal (if amidated) end of the molecule. Endopeptidase cleavage is generally quite specific, and both exopeptidases and endopeptidases (Table 4) are well characterized in terms of mechanistic properties and substrate specificity. Most importantly, it is well known that the clinical use of some peptides has been limited significantly by their short plasma half-life, which may in part be related to their lability to peptidases. Therefore, knowledge of biodegradation mechanisms has been considered to be an important research objective to facilitate the design of synthetic peptide analogs that may exhibit sustained biological activities (see Sect. 3.2). Some peptides may also undergo inactivation by other chemical transformations such as that exemplified by insulin, in which its cystine-bridged heterodimeric structure is liable to cleavage by means of reduction of the interchain disulfide bonds by the enzyme insulinase. Considerable effort has been devoted to the objective of designing synthetic peptide analogs (including pseudopeptides) and peptidomimetics, which are structurally altered to compromise or eliminate biological cleavage–inactivation by peptidases. Alternatively, there has also been considerable effort devoted to directly inhibiting either processing (cleavage activation) or degrading peptidases to modify the generation or the lifetime of a particular endogenous (or exogenous) peptide, respectively. In particular, the historically important discoveries of peptide and, subsequently, peptidomimetic inhibitors of angiotensin-converting enzyme (ACE) (i.e. teprotide and captopril: see Sect. 3.2, Fig. 4) deserve particular mention because they provided tremendous incentive to rational drug design and natural product lead-finding technologies. Such peptidase targets exemplify processing enzymes, which are required for the generation of endogenous peptides, and inhibition of such peptidases compromises the agonist activity of a particular peptide.

2.2 Peptide Biological Functions and Mechanisms of Action

Peptides serve diverse physiological roles, and their biological functions and mechanisms of action have been the subject of intensive molecular and cell biology, biochemistry and pharmacology research, as exemplified by the pioneering efforts of many scientists (including, in some cases, Nobel laureates) such as Frederick

Banting, Stanley Cohen, Pedro Cuatrecasas, Charles Deber, Lila Gierasch, Alfred Gilman, Roger Guillemin, Mac Hadley, Rita Levi-Montalcini, Frank Porreca, Jean Rivier, Martin Rodbell, Alan Saltiel, Andrew Schally, Solomon Snyder, Donald Steiner, Wylie Vale, and Henry Yamamura. Glutathione is a tripeptide that serves as a cofactor for one or more enzyme systems as related to its oxidation–reduction chemical properties. Ion-binding peptides also constitute a category of transporting molecules (ionophores) as exemplified by valinomycin (Table 3). Ion channel–binding peptides have been identified from natural sources such as venoms, and such peptides may selectively regulate sodium (Na^+), potassium (K^+), or calcium ion (Ca^{2+}) transport. Furthermore, the relationship between calcium ion and peptides extends to the finding that some peptide hormones (α-melanotropin and adrenocorticotropin) apparently require this divalent metal ion to bind and/or effect receptor-mediated signal transduction. Antibiotic peptides include gramicidin (Table 3), actinomycin D, bacitracin, penicillin, and defensins. Peptide toxins include agatoxin, α-bungarotoxin, and ricin. Finally, it is well recognized that a vast number of peptide chemical messengers exist, which manifest their biological activities as regulatory peptide hormones, neurotransmitters, growth factors, and cytokines.

Hormones, which include peptides, steroids, catecholamines, prostaglandins, and related naturally occurring compounds, are chemical messengers released by one cell to act on one or more other cell types to elicit a physiological response. The largest category of hormones consists of peptides, and the biological properties of such peptide hormones is extensive, with well-established examples related to endocrine, cardiovascular, neural, immune, and gastrointestinal system regulation. In terms of functional properties, peptide hormones regulate differentiation, growth, reproduction, blood pressure, glucose homeostasis, and behavior, in addition to performing many other regulatory activities. Peptide hormones normally exist at very low concentrations (10^{-12}–10^{-9} M) in bodily fluids or tissues, in which they persist for short periods of time (1–30 min), since they are rapidly inactivated by peptidases and/or excreted (i.e. cleared) from the body. The transitory actions of peptide hormones are well suited for continuous regulation (i.e. homeostatis) of various physiological systems.

Some of the examples of peptide hormones and their particular regulatory functions summarized earlier (Table 2) are amplified briefly here. Thyroid-stimulating hormone (TSH), which acts on the thyroid gland, is a glycoprotein, as are lutropin and follitropin, which act on the gonads (testes and ovaries). Somatotropin (growth hormone, GH) is necessary for normal growth, and defective or excessive secretion can lead to dwarfism or acromegaly, respectively. Prolactin also possesses growth-promoting activity, most specifically, mammary growth and milk production. All the pituitary peptide hormones are individually controlled by peptide factors (hormones) of hypothalamic origin. These hypophysiotropic peptides either stimulate or inhibit pituitary hormone secretion. The peptide hormones glucagon and insulin, both of pancreatic origin, are responsible for elevating or depressing glucose levels through their actions on the liver and other organs. Glucose homeostasis is therefore very tightly regulated by these two counter-regulatory peptides. Similarly, parathyroid

hormone (PTH) and calcitonin, derived from the parathyroid and thyroid glands respectively, act in a counterregulatory manner to maintain serum Ca^{2+} levels. Specifically, PTH elevates and calcitonin lowers blood Ca^{2+} levels. The GI peptide hormones regulate the movement, metabolism, digestion, and intestinal absorption of metabolic substrates that are essential for life. Peptide hormones regulate GI smooth muscle motility (and therefore substrate transport) and the pancreatic enzyme secretions that degrade metabolic substrates into absorptive substrates. Gastrin, cholecystokinin (CCK), and vasoactive intestinal peptide (VIP) are examples of a dozen or so recognized peptide hormones that regulate GI, pancreatic, and other processes. A large number of peptide growth factors have been discovered, which play a role in normal as well as neoplastic (cancerous) growth. Factors such as epidermal growth factor (EGF), nerve growth factor (NGF), transforming growth factors, somatomedins, and erythropoietin each affect certain cell types to regulate their normal growth and proliferation. Excess secretion of certain of these peptide growth factors may correlate to neoplastic transformation, tumor growth, and/or metastasis. A most important discovery was that peptides produced by the brain exhibit analgesic activity, as do the opiate drugs (e.g. morphine). This observation led to the discovery of opiate receptors and the demonstration that endogenous morphine-like substances (e.g. Met-enkephalin, β-endorphin, dynorphin) interact with the same receptors to affect analgesia.

Peptide hormones, probably without exception, mediate their initial actions at the level of the cell plasma membrane (phospholipid bilayer). Peptide hormones (''first messengers'') interact at the cell surface with protein (or glycoprotein) macromolecular receptors, which bind to the peptide ligand in a very specific manner. This results in activation (signal transduction) of proximally located enzymes or transport proteins, which may be modified in a positive or negative manner to produce within the cell, a ''second messenger'' (e.g. cAMP, cGMP, IP_3, DAG, Ca^{2+}/K^{+}; Table 5). Alternatively, the peptide–receptor complex may result in kinase-like activities to phosphorylate other cellular signaling proteins such as those exemplified by growth factor receptor kinases. Many peptide hormones and neurotransmitters effect receptor-mediated stimulation or inhibition of adenylate cyclase via intermediary signaling heterotrimeric proteins known as *G proteins*. Recognition domains of such G protein–coupled peptide receptors (typically, a seven transmembrane–spanning helical protein superfamily) exist for both the peptide ligand and the specific G protein. Three-dimensional models are being developed to provide further insight into the structure–activity relationships of these G protein–coupled receptors as related to protein-coupled receptors as related to probing the molecular basis of peptidergic receptor-mediated biological signaling by site-directed mutagenesis. In cases of oncogene activation, the uncontrolled production or mutation of cellular proteins can mimic, for example, a signaling pathway mediated by a growth factor peptide–receptor complex, which can lead to a pathophysiological (malignant carcinogenic) transformation of that particular cell. Examples of oncogenes that can lead to disregulated signal transduction pathways include peptide growth factors (e.g. *sis*), receptors (e.g. *erb B*), transduction proteins (e.g. *ras*), and transcription factors (e.g. *fos, myc*). Binding

Tab. 5 Peptidergic receptor subtypes and signal transduction pathways.

Peptide	***Receptor subtype***	***Signal transduction second messenger***	***Peptide//Peptidomimetic/Nonpeptide (Agonists or antagonists)***
Angiotensin II	AT_1	↓cAMP, ↑IP_3/DAG	DuP753 (nonpeptide antagonist)
	AT_2	Not determined	PD123177 (nonpeptide antagonist)
Bradykinin	B_1	Not determined	BK_{1-8} (peptide agonist) [Leu^8]BK_{1-8} (peptide antagonist)
	B_2	↑IP_3/DAG	[$Phe^8(CH_2NH)Arg^9$]BK (pseudopeptide agonist) d-Arg[Hyp^3, Thi^5, D-Tic^7, Oic^8]BK (peptide antagonist)
Cholecystokinin	CCK_A	↑IP_3/DAG	A-71623 (peptide agonist) Devazepide (nonpeptide antagonist)
	CCK_B	Not determined	Gastrin (peptide agonist) CI-988 (peptidomimetic antagonist)
Endothelin	ET_A	↑IP3/DAG	ET-1 (peptide agonist; nonselective) BQ-123 (peptide antagonist)
	ET_B	↑IP_3/DAG	Sarafotoxin S6c (peptide agonist)
Neuropeptide-Y	Y_1	↓cAMP	[Leu^{31}, Pro^{34}]NPY (peptide agonist)
	Y_2	Not determined	NPY_{13-36} (peptide agonist)
Met-enkephalin	δ-Opioid	↓cAMP, ↑K^+ channel	DAMGO (peptide agonist) CTOP (peptide antagonist)
β-Endorphin	μ-Opioid	↓cAMP, ↑K^+ channel	DPDPE (peptide agonist) ICI-174864 (peptide antagonist)
Dynorphin	κ-Opioid	↓Ca^{2+} channel	U-69593 (nonpeptide agonist) Norbinaltorphimine (nonpeptide antagonist)
Substance P	NK_1	↑IP_3/DAG	[Pro^9]SP (peptide agonist) CP-96345 (nonpeptide antagonist)
Substance K (NK_A)	NK_2	↑IP_3/DAG	[Lys^5, $MeLeu^9$, Nle^{10}]NKA (peptide agonist) L-659877 (peptide antagonist)
Neurokinin-B (NK_B)	NK_3	↑IP_3/DAG	Senktide (peptide agonist) [Trp^7, β-Ala^8]NKB_{4-10} (peptide antagonist)
Vasopressin	V_{1A}	↑IP_3/DAG	$d(CH_2)_5$[$Tyr(Me)_2$]AVP (peptide antagonist)
	V_{1B}	↑IP_3/DAG	–
	V_2	↑cAMP	Desamino[D-Arg^8]AVP (peptide agonist) $d(CH_2)_5$[D-Ile^2, Ile^4]AVP (peptide antagonist)

of a peptide to a receptor (or enzyme) results from a multiplicity of noncovalent intermolecular interactions, and these events are fundamentally related to structure–activity studies focused on a plethora of biologically active peptides. Binding is considered to precede transformation of the receptor (or enzyme) from its inactive to active state by molecular mechanisms often not understood. In many cases, it has been determined which substructural features of a peptide are required for binding (i.e. the ''address'' sequence) versus signaling/activation (i.e. the ''message'' sequence). In the case of adrenocorticotropin, for example, the central 5–24 amino acid sequence of the native peptide (Table 3) is capable of effecting full steroidogenic agonism, whereas further N-terminal truncation (i.e. $ACTH_{8-24}$ or $ACTH_{11-24}$) gives rise to partial agonism or antagonism. Similarly, corticotropin-releasing factor (CRF) appears to require a significant portion of its C-terminal sequence for binding (i.e. residues 12–41), whereas biological activity requires N-terminal extension (i.e. residues 6–41). The three-dimensional structural features of a peptide that provide the essential functional group ensemble for molecular recognition (binding) at a target receptor or enzyme may be composed of backbone and/or side-chain components, and such a three-dimensional substructure of the peptide has been referred to as the *pharmacophore*. Development of both intuitive peptide pharmacophore models and models derived experimentally (biophysical and computational chemistry) is providing an opportunity to explore the molecular recognition and mechanistic properties of peptide interactions with macromolecular targets. Such studies are of particular significance to peptidomimetic drug design.

3 Peptide Drug Design

A large number of pharmaceutical companies and biotechnology firms have successfully advanced the discovery and development of synthetic or recombinant peptides as well as synthetic peptidomimetic or nonpeptide drugs for numerous medical applications. Relative to synthetic peptide, peptidomimetic, and nonpeptide drug discovery, the integration of drug design using NMR spectroscopy, X-ray crystallography, computational chemistry, and other biophysical and *in silico* methods has been critical to provide insight to the intimate structure–activity relationships and related biological properties necessary to create potent, selective, metabolically stable, safe-acting and, in many cases, orally effective molecules. Of course, knowledge of the pathophysiology of biologically active peptides and their therapeutic target (e.g. receptor, peptidase or signal transduction protein) is essential to identify opportunities for peptide (synthetic or recombinant), peptidomimetic and nonpeptide drug discovery.

3.1 Peptide Pathophysiology and Therapeutic Targets

The pathophysiology related to biologically active peptides may be due to defects in the biosynthesis of the peptide or its target receptor (or enzyme), among a number of other factors. Table 6 lists a variety of endocrine disorders that result from excessive or deficient peptide hormone levels. Amino acid mutations of regulatory peptides are known to exist and to provide the molecular basis for pathophysiological conditions requiring replacement therapy. Causative factors in some cases of diabetes

Tab. 6 Pathophysiological states of known relationship to peptides.

Disease (symptom)	*Relationship to peptide*
Addison's disease (abnormal carbohydrate metabolism)	Deficiency in adrenocorticotropin
Cushing's disease (increased protein catabolism)	Excess adrenocorticotropin
Secondary hypogonadism	Deficiency in gonadotropin
Secondary hypergonadism	Excess gonadotropin
Hyperglycemia and glucosuria (diabetes mellitus or insulin-dependent diabetes, if resulting from cytotoxic autoantibodies to β-cells)	Deficiency in insulin
Abnormal blood Ca_2 (increased), hyperparathyroidism	Excess parathyroid hormone
Abnormal growth (decreased), Laron-type dwarfism	Deficiency in somatomedin
Abnormal growth (decreased), hypopituitary dwarfism	Deficiency in somatotropin
Abnormal growth (increased) in children, giantism	Excess somatotropin
Abnormal growth (increased) in adults, acromegaly	Excess somatotropin
Abnormal metabolism (increased), Graves' disease antibodies	Excess thyrotropin-mimicking, anti-TSH receptor
Hypovolemia–dehydration (increased), pituitary-type diabetes insipidus	Deficiency in vasopressin

Source: Adapted from Hadley, M.E. (2000) *Endocrinology*, 5th ed., Prentice Hall, Englewood Cliffs, NJ.

mellitus are defects in the primary structure of insulin, either in the active site of the peptide or at sites of cleavage, where the insulin chains are proteolytically cleaved from the prohormone structure. Some, albeit rare, types of diabetes are also due to defects in the amino acid sequence of the insulin receptor that compromise binding of the peptide hormone to the receptor or receptor-mediated signal transduction. In one form of familial (genetic) hypothyroidism, a mutation in one codon of the gene that transcribes for the β-subunit of the hormone thyrotropin (TSH) results in a single amino acid substitution to yield a conformationally abnormal β-subunit that cannot associate with the α-subunit to form a functionally active heterodimeric peptide hormone. Furthermore, since this particular defect in producing endogenous active TSH is familial, and therefore present at birth (congenital), the consequences (e.g. cretinism) are devastating. Within the scope of mimicking or blocking regulatory peptide effects at the level of target receptors, there exists a tremendous research effort in identifying peptidomimetic or nonpeptide derivatives (agonists or antagonists), and such studies have enabled both pharmacological analysis and, in some cases, the discovery of therapeutic agents of synthetic or recombinant origin (see Sect. 3.2). Furthermore, the design of peptide receptor-targeted agonists or antagonists that may be radiolabeled or conjugated to anticancer drugs has made it possible to use such agents in the diagnosis, localization, or chemotherapy of tumors. For example, radioactive indium attached to a somatostatin analog has been developed to localize certain tumors by external scintography.

Enzyme targets that have been determined to be of particular clinical importance as related to the pathophysiology of regulatory peptides include a number of peptidases (Table 4). Representative peptidase targets may be classified as

follows: serine peptidases, such as thrombin, tissue plasminogen activator (TPA), and elastase; metallopeptidases, such as ACE, collagenase, and enkephalinase; aspartic peptidases, such as renin, cathepsin D, and HIV protease; and cysteine peptidases, such as cathepsin B, and calpains. As described earlier, peptidases may function primarily as processing or degrading enzymes of regulatory peptides. Within the scope of blood pressure regulation, inhibitors of either ACE or renin may serve to reversibly terminate the stepwise processing of the α_2-macroglobulin angiotensinogen to give rise to the vasoconstrictor angiotensin II (AII). In the case of ACE inhibitors, the clinical efficacy of such drugs as antihypertensives has been well established. In the latter case, the discovery of potent peptidomimetic inhibitors of renin has not readily translated into the development of orally active therapeutic candidates to date. However, such research has catalyzed the identification and design of peptidomimetics that inhibit HIV protease, an aspartyl peptidase having structural and mechanistic resemblance to renin, and such potential drugs may enable a novel chemotherapeutic intervention strategy for the threatening spread and fatal pathogenesis related to AIDS. As a separate case, but still related to processing peptidase targets, peptidomimetic inhibitors of thrombin are being designed in the hope that they might be used to prevent thrombus (clot) formation following surgery. Within the realm of degrading peptidases, the discovery of peptidomimetic inhibitors of neutral endopeptidase (NEP) has been a strategy of interest to advance novel analgesic agents that function via inhibiting the cleavage inactivation of endogenous opioid peptides (e.g. enkephalins). Similarly, peptidomimetic inhibitors of collagenase, a collagen-degrading peptidase, are thought to be of potential utility in the discovery of therapeutic agents effective in pathological conditions such as rheumatoid arthritis.

3.2 Peptide, Peptidomimetic, and Nonpeptide Drug Discovery

Peptide, peptidomimetic, and nonpeptide drug discovery is an intriguing area of research efforts in numerous pharmaceutical and biotechnology companies, and interdisciplinary strategies have emerged over the past two decades that have provided the framework to advance lead compounds and, in some cases, drugs (Fig. 3). Noteworthy to such peptide, peptidomimetic, and nonpeptide drug discovery has been the pioneering work of many scientists from both academia and industry, including Richard DiMarchi, Roger Friedinger, Ralph Hirschmann, Victor Hruby, Isabella Karle, Horst Kessler, Garland Marshall, Henry Mosberg, John Nestor, Daniel Rich, Joseph Rudinger, Tomi Sawyer, Peter Schiller, Robert Schwyzer, and Daniel Veber.

The first recombinant peptide drug commercialized was insulin in 1982. Currently, a number of peptide drugs (or preclinical leads) have been advanced using genetic engineering technologies. Examples are somatotropin, tumor necrosis factor, EGF, erythropoietin, hepatitis B vaccine, interferons, various cytokines, and TPA (Table 7). On the basis of the success of insulin replacement therapy for the treatment of some types of diabetes mellitus, the potential for therapeutic application of other structurally complex peptides has been advanced by sophisticated molecular biology methodologies, which permit biosynthesis of peptides not readily obtained by chemical synthesis.

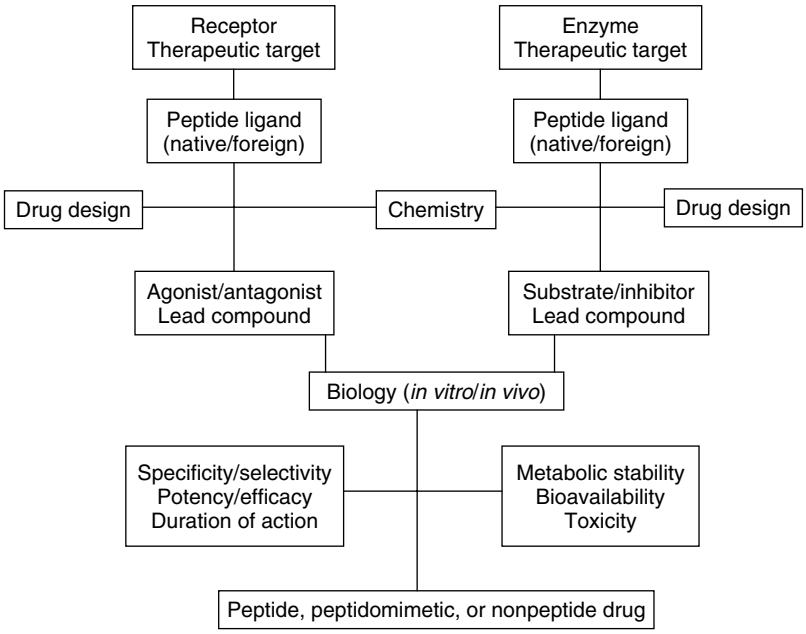

Fig. 3 Interdisciplinary strategies in peptide, peptidomimetic, and nonpeptide drug discovery.

The known chemical diversity of peptide, pseudopeptide, peptidomimetic, and nonpeptide structures that have been advanced as lead compounds or marketed drugs is extensive. Synthetic peptides include native molecules and analogs that incorporate side-chain and/or backbone modifications. In many cases, the resultant synthetic derivatives are more potent, target tissue (receptor) selective, and/or stable to peptidases relative to the native peptide. Such examples include Sandostatin (SRIF analog), Desmopressin (vasopressin analog), Goserelin (GnRH analog), Tetracosactide (corticotropin analog), and Melanotan-I (MSH analog). The discovery of ''first-generation'' peptide antagonists has, in a majority of cases, been based on chemically modified analogs. Peptide-based competitive antagonists of bradykinin, oxytocin, PTH, enkephalin, vasopressin, glucagon, CCK, gastrin, angiotensin II, GnRH, substance P, and CRF have been reported during the past decade, and such compounds have typically incorporated unusual amino acids (e.g. D-amino acids, cyclic amino acids, α,β-unsaturated amino acids; Fig. 2) and backbone CONH replacements.

The chemical transformation or replacement of peptide agonists or antagonists by simpler (molecular weight-wise), metabolically stable, and orally bioavailable ''second-generation'' peptidomimetics or nonpeptides has been accomplished (Table 7). For example, research focused on peptide receptor targets has led to the identification of effective antagonists. To some extent, molecular recognition properties required to mimic the agonist properties of peptides may be more complex and, perhaps, uncompromising relative to those effecting antagonist properties. In fact, the identification of many nonpeptide

Tab. 7 Examples of peptide, peptidomimetic or nonpeptide drugs, clinical candidates or preclinical lead compounds.

Recombinant peptides	***Proposed/Known therapeutic application***
Atrial natriuretic factor	Potential use in prophylaxis and/or treatment of acute renal failure
Epidermal growth factor	Potential use in skin grafting, eye surgery, and/or treatment of burns or ulcers
Somatotropin	Treatment of growth defects
Insulin	Treatment of type-I diabetes
Glucagon-like insulinotropic peptide	Potential treatment of insulin-insensitive diabetes
Teriparatide	Treatment of osteoporosis
Transforming growth factor	Potential treatment of wound healing and burns
Nerve growth factor	Potential treatment of neural plasticity defects as possibly related to Alzheimer's disease
Interleukin-1α/β	Potential use in cancer therapy and inflammation
Hirudin	Potential use in prevention or treatment of venous blood clots
Tissue plasminogen activator	Potential use as an anticoagulant in heart attacks
Factor VII	Potential use as a blood clotting factor in major forms of hemophiliacs
Erythropoietin	Potential uses in treatment of anemia in kidney dialysis patients, AIDS, and cancer
Platelet-derived growth factor	Potential uses in promoting growth of fibroblasts, keratinocytes, and formation of new blood vessels
Interferon-α	Potential use as an immune stimulant for cancer therapy
Interferon-β	Potential use as an immune stimulant for treatment of viral diseases and multiple sclerosis
Interferon-γ	Potential use as an immune stimulant for treatment of infectious diseases, cancer, and rheumatoid arthritis
Synthetic peptides (relationship to native peptide)	***Proposed/known therapeutic applications***
Aspartame (dipeptide mimic of glucose)	Artificial sweetener
Cyclosporin A (peptide natural product)	Immunosuppressive drug

Sandostatin™ (hexapeptide agonist analog of SRIF)	Symptomatic treatment of acromegaly and carcinoid syndrome
Techtide P829 (radiolabeled SRIF analog)	Detection of tumors
Desmopressin (nonapeptide agonist analog of vasopressin)	Treatment of severe diabetes insipidus
Buserelin (nonapeptide agonist analog of GnRH)	Treatment of prostate cancer
Goserelin (GnRH agonist)	Treatment of cancer and hormonal menstruation disorder
HOE-140 (decapeptide antagonist analog of BK)	Potential treatment of pain, inflammation, rhinitis, and/or asthma
Melanotan-I (tridecapeptide agonist analog of MSH)	Potential use as a stimulant of skin pigmentation
Tetracosactide (peptide agonist analog of ACTH)	Diagnostic agent of adrenal function
BQ-123 (cyclic pentapeptide, natural product antagonist of endothelin)	Potential treatment of hypertension, restenosis, and related disorders
Calcitonin (identical to native peptide)	Treatment of hypercalcemia, Paget's disease, osteoporosis, and pain affiliated with bone cancer
Ebiratide (hexapeptide agonist analog of ACTH)	Potential application for CNS disorders; cognition treatment
Pentigetide (pentapeptide antagonist analog of IgE)	Potential antiallergic agent
MDL28050 (decapeptide antagonist analog of Hirudin)	Potential use as thrombin inhibitor based, anticoagulant agent
Eptifibatide (cyclic heptapeptide)	Potential antithrombotic drug
L365209 (pseudohexapeptide, natural product antagonist of oxytocin)	Potential use as uterine relaxant for prevention of premature labor
Atosiban (oxytocin antagonist)	Potential use for preterm labor
DPDPE (pentapeptide agonist analog of enkephalin)	Potential analgesic lead; δ-selective opioid agonist
GHRP-6 (hexapeptide agonist at gherelin receptor)	Potential GH secretagogue lead
Groliberin (growth hormone-releasing factor analog)	Potential use for treatment of growth hormone deficiency
Enfuvirtide (inhibitor of viral fusion)	Potential antiviral and anti-HIV drug

(*continued overleaf*)

Tab. 7 (*Continued*)

Peptidomimetics or nonpeptides (relationship to native peptide)	***Proposed/known therapeutic applications***
Morphine (peptidoligand natural product agonist at μ-type enkephalin receptor)	Analgesic drug
Captopril, Enalapril (peptidomimetic inhibitors of ACE)	Antihypertensive drugs
DuP-753 (nonpeptide antagonist at AT_1-type AII receptor)	Potential antihypertensive drug
A-72517 (peptidomimetic inhibitor of renin)	Potential antihypertensive drug
Ro-318539, A-75925 (peptidomimetic inhibitors of HIV protease)	Potential anti-HIV/AIDS drug
CP-96345 (nonpeptide antagonist at NK_1 receptor)	Potential use as an antiallergic or analgesic drug
SC-47643 (peptidomimetic antagonist at fibrinogen receptor)	Potential use for prevention of thrombus formation
Integrilin (peptidomimetic antagonist at fibrinogen receptors)	Potential use for myocardial infarction
OPC-21268 (nonpeptide antagonist at V_1 vasopressin receptor)	Potential use as a diuretic agent
Ro-24 9975 (peptidomimetic agonist at TRH receptor)	Potential use as cognitive enhancer agent
CI-988 (peptidomimetic antagonist at CCK_B receptor)	Potential anxiolytic drug
MK-329	Potential use for treatment of pancreatitis (nonpeptide antagonist at CCKA receptor)
L-692429 (nonpeptide agonist at gherelin receptor)	Potential use as a GH secretagogue
SCH-34826 (peptidomimetic inhibitor of metallo-endopeptidase EC 3.4.24.11)	Potential antihypertensive drug; inhibitor of atrial naturetic peptide (ANP) degradation
CT-0543 (peptidomimetic inhibitor of gelatinase)	Potential antimetastatic agent
MD-805 (peptidomimetic inhibitor of thrombin)	Potential antithrombolytic drug
Bivalirudin (thrombin inhibitor)	Potential anticoagulant and antianginal drug
Ampicillin, amoxycillin (nonpeptide inhibitors of bacterial cell wall peptidoglycan synthesis)	Antibacterial penicillin-related drugs

Note: See Table 3 and Fig. 4 for some chemical structures.

antagonists at peptide receptors has been significantly advanced by mass screening assays using chemical collections as well as various natural product sources, thereby illustrating the fact that the peptide ligand is not exclusive toward providing the molecular framework for peptide antagonist drug discovery. Interestingly, the recent development of peptide library technologies (including emerging pseudopeptide and peptidomimetic libraries) has accelerated opportunities to identify novel leads as well as the ability to evaluate analogs in a structure–activity sense to expedite the overall process of drug candidate selection. The application of biophysical chemistry (e.g. NMR spectroscopy and X-ray crystallography) and computational chemistry methods have collectively established powerful drug design technologies for the synthetic transformation of native peptides to chemically modified pseudopeptides or peptidomimetics. In the case of cyclic, conformationally constrained peptides, the synergism of NMR spectroscopy and computational chemistry-based analysis of three-dimensional structural properties and model building points to an extremely promising approach to advancing peptide-based drug design in a rational manner. In the case of X-ray crystallography and computational chemistry, the study of peptide or peptidomimetic interaction with proteins (peptidases, kinases, Src homology proteins, antibodies) exploits high-resolution (1.8–3.0 Å) molecular maps of the complex to provide insight into further design strategies. In this regard, recent work on HIV protease, an aspartyl peptidase, is particularly outstanding in that more than 120 inhibitor–enzyme complexes have been determined by X-ray crystallography. Furthermore, this work provides an excellent example of peptide and peptidomimetic drug design and development strategies that integrate molecular biology, biochemistry, synthetic chemistry, biophysical and computational chemistry, pharmacology, and drug delivery research (Fig. 4).

Among the major challenges of developing peptide drugs has been the mode of administration of the particular compound. Peptide drug delivery exists in many forms, including parenteral (intravenous or intramuscular injection), interstitial (subcutaneous implant), oral, nasal, and percutaneous (transdermal) administration. Perhaps, the most well-known injectable peptide is that of insulin, and with respect to implants the recent success of the gonadotropin-releasing hormone analog Zoladex deserves mention. In the case of oral administration, one of the key reasons for pursuing the chemical transformation of peptides into peptidomimetic derivatives has been to identify prototypic lead compounds that may exhibit oral bioavailability. Such efforts have shown success as exemplified by the development of orally effective ACE inhibitors, renin inhibitors, HIV protease inhibitors, thyrotropin-releasing hormone (TRH) agonists, fibrinogen antagonists, and so forth. Nevertheless, the possibility of alternative modes of administration of peptide (or peptidomimetic) drugs remain an intriguing area of research, and some success has been achieved with respect to nasal (oxytocin, desmopressin, buserelin, and calcitonin), pulmonary, buccal, rectal, and transdermal routes of peptide drug administration. Of particular impact on the oral delivery of peptide drugs is the limitation on passive or active transport of molecules of high molecular weight (typically including tetrapeptides and larger peptides) posed by the intestinal epithelia. Similarly, stability toward gastric acid and degradative enzymes, including

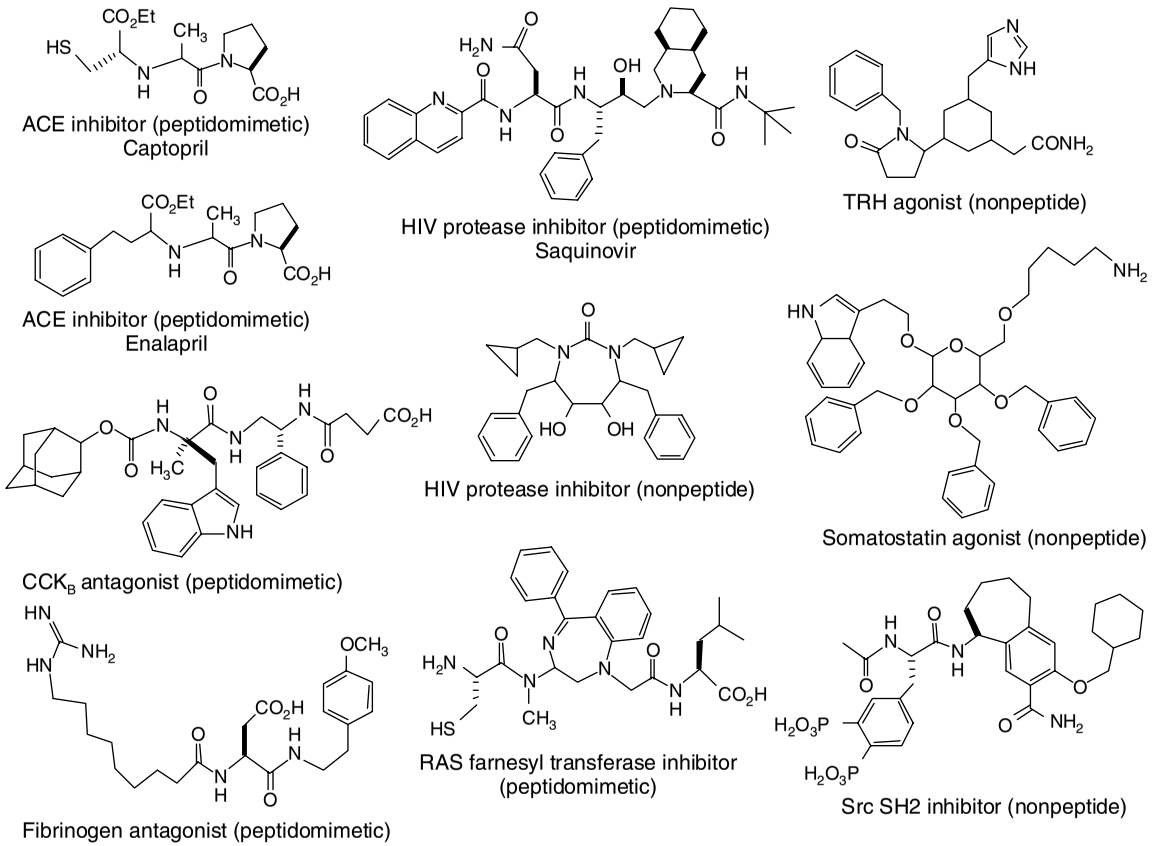

Fig. 4 Chemical structures of some peptidomimetic or nonpeptide drugs, clinical candidates, or preclinical lead compounds.

peptidases associated with the epithelial membrane (luminal side) or within such cells, provides another challenge a peptide-based drug candidate must surpass to eventually access systemic circulation after oral administration.

The apparent medical potential for peptide, peptidomimetic, or nonpeptide drugs is already tremendous, and future opportunities will continue to make this area of pharmaceutical research extremely competitive. There are approximately 100 synthetic and recombinant peptides that are marketed worldwide, and an estimated 200 molecules that are in clinical testing. Nine marketed peptides are responsible for annual sales surpassing the $4 billion mark. Some past and current examples of peptide, peptidomimetic, and nonpeptide preclinical lead compounds, clinical candidates, and marketed drugs are exemplified above in Table 7. Most recently, synthetic and recombinant peptides that have been approved by the FDA include Teriparatide (PTH agonist analog for osteoporosis), Goserelin (GnRH agonist analog for cancer and hormonal menstruation disorder), Integrilin (integrin gpIIb/IIIa antagonist for myocardial infarction) Enfuvirtide (inhibitor of viral fusion to effect antiviral and anti-HIV activity), Eptifibatide (cardiovascular, neuroprotective), Bivalirudin (thrombin inhibitor for anticoagulant and antianginal), Atosiban (oxytocin antagonist for preterm labor), Techtide P829 (radiolabeled somatostatin analog for tumor detection), and Groliberin (GRF analog for treatment of growth hormone deficiency). Past and still existing major peptide and peptidomimetic drugs include insulin (for treatment of diabetes) and dipeptide sweeteners such as aspartame. Without question, the field of peptide, peptidomimetic, and nonpeptide drug discovery has emerged as a superclass of molecules for a plethora of disease as exemplified by the therapeutic scope and molecular diversity as described in this chapter. Future research and drug development holds further promise to combat many existing diseases and to deal with many unmet needs throughout the world.

Keywords

System
A set of interacting parts functioning as a whole and distinguishable from its surroundings by identifiable boundaries.

Systems Theory
Systems theory denotes the cross-disciplinary investigation of the abstract organization of systems, irrespective of their substance, type, or spatiotemporal scale of existence. The goal is the study of emerging properties that arise from the interconnectedness of the individual parts making up the system.

Robustness
Robustness of biological systems denote the maintenance of specific system functionalities in the presence of fluctuations or change in environmental parameters.

Control
Control is defined as the response action taken by a system to counteract parameter changes to maintain system functions at a certain, predefined level.

Modularity
A design concept of complex systems to integrate simpler, self-contained functional building blocks into the framework of one larger system.

Model
The concept of representing causal relationships from real systems in the language of mathematics.

Systems biology is a new field of biology, which puts the theoretical foundations of system-level analysis of living matter into the context of modern high-throughput quantitative experimental data, mathematics, and *in silico* simulations. It aims at analyzing the organization and gaining engineering-control of metabolic and genetic pathways. The ultimate goal will be to gain a 'holistic' view on the complex workings of life. This article reviews the need for a system-level understanding of biology, comments on the current scientific progress in this field, and points out future directions of experimental design strategies and theoretical approaches.

1 Introduction

Systems biology is a newly established field in life sciences that aims at promoting a global system-level understanding of living matter through the integration of various scientific domains.

The considerate attention Systems biology receives nowadays is due to the fact that it will most likely cause a paradigmatic shift in biological research. Modern molecular cell biology so far has been a descriptive science, devoting insight mainly to isolated small compartments of a system as a whole, for example, by investigating the influence of individual molecules types within the whole cell cycle. The study of the interconnected nature of cellular processes has long been avoided in favor of a reductionist approach. This is on one hand due to the sheer amount of new challenges that come about when tackling complex systems. On the other hand, it has been the common leitmotif in other natural sciences, such as physics, to shed light mostly on well-controlled systems that are either small and isolated, or large and homogeneous so that they can be tackled with the laws of statistics. It is dawning on us only now that the true challenge lies in the description of dynamical, mesoscopic, open, spatiotemporally extended, nonlinear systems that operate in the absence of thermodynamic equilibrium, and these systems are the most important to understand as they are the ones that support life

Although the reductionist approach has been successful in identifying key factors for many fundamentally important biological processes, contemporary science has to recognize the importance of wholeness, which is defined as problems of organization instead. Emergent phenomena arise from the interaction of various units or modules, which are neither resolvable nor understandable through the study of local events or the respective parts in isolation. Hence, traditional reductionist models and methods of cell and molecular biology are not very well suited and can be incomplete, misleading, or even completely wrong.

Historically, Jan Christiaan Smuts was among the first to formulate a theory of the whole that was hoped to fill the gap between science and philosophy. In his book ''Holism and Evolution,'' published in 1926, Smuts argued that nature consisted of discrete objects, or 'wholes,' that are not entirely resolvable into their respective parts. The wholes and parts mutually depend on each other in their functionality, thus forming one organic, unified web of relations, which comprises matter, life, and mind that cannot be accounted for by a reductionistic analysis. Smuts saw his idea confirmed in evolution, regarding Holism as the active driving force toward more perfect wholes or species.

The theoretical foundations of systems engineering have already been laid 50 years ago. The concept of systems theory in biology (cf. Sec. 2) was proposed in the 1940s by the biologist Ludwig von Bertalanffy and further developed in the 1950s by Ross Ashby as a countermovement against reductionism in science. In the sense of holism, von Bertalanffy emphasized the need for a study of the informational organization within real, open systems. The assembly of such interrelated elements then comprise a unified whole, which in turn can show new emergent properties.

In 1948, the mathematician Norbert Wiener established the field of cybernetics as the science of communication and control of systems in regard to their environment. Cybernetics is closely related

to systems theory, using the same concepts of information, control, or feedback. However, the former focuses on systems function for providing regular and reproducible behavior, whereas the latter deals more with system structure. Even so, both terms are often used in conjunction, for both structure and function cannot be understood as separate entities.

Although the mathematical tools required for Systems biology had already been refined decades ago, the approach of systems theory in biology has gained momentum only now in the era of genomics and proteomics as a consequence of high-throughput measurements, which provide the necessary amount of quantitative data for the establishment of appropriate holistic models of cellular processes.

Today, biology embarks on systems thinking in two different ways. One way is to regard Systems biology as a new way toward integrating information from different organizational levels, starting from DNA to proteins via metabolic pathways to functional modules, into the context of a holistic organizational view. The primary goal of the second view on Systems biology is to establish a conceptual framework and working methodologies for the augmentation of knowledge on the workings of biological phenomena, thus combining systems theory and molecular biology: ''Systems biology is not a collection of facts but a way of thinking''. This view has already been shared by Mesarović in the late 1960s. He predicted that Systems biology would be an established field of science as soon as ''biologist start asking the right questions''. Put differently, biologists need not recast facts already known from molecular biology in a different language, but they need to ask questions based on system-theoretic concepts.

Both ways share the extensive need for high-quality, quantitative biological data through extensive experimental endeavors and new mathematical analysis tools as a basis of developing detailed models that are essential for the study of systemic properties and behavior. Currently, it is the hope in the postgenomic era that new breakthroughs in experimental techniques lay the foundation for the integration of mathematics, engineering, physics, and computer science into biology to understand the range of complex biological regulatory systems at multiple hierarchical and spatiotemporal levels of cellular organization.

Section 2 defines the concept of system-level understanding in detail. The need for Systems biology will become clear from the discussion on the outstanding properties of biological systems, such as complexity, modularity, stochasticity, and hierarchical organization in Sect. 3. These insights lead to guidelines and strategies for the design of experiments and models with the need of a unified computational infrastructure as explained in Sect. 4. The last section (Sect. 5) concludes with an outlook on the future prospects of Systems biology and the hope for the initiation of a Systeome Project.

2 What is System-level Understanding?

The word ''system'' derives from the Greek and is composed of the prefix *syn*, meaning together, and the root of *histanai*, meaning ''cause to stand.'' A system is defined as the assembly or set of interrelated elements comprising of a unified whole that is distinct from its environment. It can be hierarchically organized and made up of

other subsystems or modules, which allows for constructing a complex entity out of simpler units. For example, organelles like mitochondria constitute distinct subsystems within the organization of a cell. The subdivision of natural entities into systems is an abstract construct. Systems *per se* do not really exist in reality. They are rather defined as a set of elements interacting over time.

Systems theory denotes the transdisciplinary investigation of the abstract organization of phenomena, independent of their substance, type, or spatiotemporal scale of existence. Its goal is to study emerging properties arising from the interconnectedness and complexity of relationships between parts. It argues that however complex or diverse a system is, there are always different types of organizational structures present, which can be represented as a network of information flow. Because these concepts and principles remain the same across different scientific disciplines like biology, physics or engineering, systems theory provides a basis for their unification. The systems ansatz distinguishes itself from the more traditional analytic approach by emphasizing concepts of system-environment boundaries, signal input–output relationships, signal and information processing, system states, and hierarchies. Albeit systems theory is valid for all system types, it usually focuses on complex, adaptive, self-regulating systems that are called *cybernetic*.

Elegant, simple, and globally valid models are rare in biology as compared to other fields of science. Few examples exist where some function can be attributed to the workings of a single small molecule or protein, as is the case with hemoglobin during gas transport in the blood stream. In most cases, several genes are coexpressed and a multitude of proteins is involved for each cellular signaling pathway. Nevertheless, modern biology so far mostly followed a reductionist approach, typically tackling small isolated parts of an organism, trying to deduce biological phenomena from molecular behavior, which oftentimes results in a simplistic ''one gene for one function''-approach. However, genetic analysis has shown that the genotype of different species is mostly identical. It must be thus the signal processing stages on the way from the genome to the phenotype, in other words, an ever more elaborate regulation of gene expression that amplify the subtle particularities in the respective genetic codes.

Therefore, it becomes clear that future explanations of biological phenomena ought to be explained in the vocabulary of system theory, such as amplification, control, adaptation, sensitivity, autoregulation and error correction, taking a holistic view of the system under consideration. In short, Systems biology is needed to uncover the laws of the whole that cannot be deduced by delving deeper into the details.

Accordingly, system-level investigation of biological matter comprises the understanding of system structure and function in the sense of systems theory and cybernetics, respectively.

System structure: This denotes the identification of the static connection topology and regulatory relationships within the network of genes, proteins, and other small molecules that constitute the signal transduction and metabolic pathways as well as the physical structure of organisms or cells. Some of the experimental techniques currently available to deduce the cells' global

system structure are DNA microarray or protein complex identification using TAP tagging and mass spectrometry analysis.

System dynamics: This refers to the qualitative and quantitative evolution of the above network over time. Dynamics include the temporal variation of the metabolites' concentrations as well as the structure of the network itself. Different methods are applicable for the proper establishment of the model, such as metabolic, sensitivity, or dynamic analysis.

The system dynamics of gene regulation can be determined to a certain degree by quantitative Westernblots and RT-PCR. Spatiotemporal dynamics of individual molecules has become available with the help of fluorescent marker proteins. In particular FRAP (fluorescence recovery after photobleaching), FRET (fluorescence resonance energy transfer and FCS (fluorescence correlation spectroscopy) allow the determination of molecular diffusion constants, molecular interaction, and the localization of individual proteins or protein complexes in time and space.

Once the structure and its spatiotemporal dynamics have been (partly) understood, it is a future vision to develop methods controlling the state of the respective biological systems. The control schemes could be utilized to minimize malfunctions or treatment against disease within the particular system. The ultimate goal will be to design new multitarget methods for cellular control schemes as well as the forward engineering of living matter from scratch on the basis of the knowledge from model predictions and understanding. The area of systems control and design in biology is usually referred to as *Synthetic biology* (See Sec. 5.1).

3 What Makes Biological Systems so Special?

While biological systems still need to be based on laws of (quantum-)mechanics, chemistry, and thermodynamics, biology additionally incorporates the notion of organismal function, which represents the need for survival and reproduction, as well as the possibility to evolve in and adapt to changing environments. This inherent purpose differentiates biology significantly from all other natural sciences. Moreover, there is no distinct separation of information storage and regulatory units. Both genes and proteins are used for long- and short-term storage of interaction rules as well as being active regulatory elements. Genes, for example, can regulate their own expression. Classical physics views the emergence of every effect to be determined by a cause residing in the past. Biological systems on the contrary are teleonomic, that is, they are oriented toward a state in the future. It was the insight of Cybernetics that purposeful activity can be described through the use of circular mechanisms, where the effect equals the cause. The simplest example of a circular logic is a feedback loop, where the output of the system is fed into its input again (See Sec. 3.2).

Having these prerequisites in mind, the concepts of systems theory and cybernetics should be utilized, if one wants to establish successful formal mathematical models in biology. The introduction of circular causalities has far reaching consequences on the general design and global

properties of biological systems, such as robustness, complexity and control, which are discussed in detail in this section.

3.1 Biological Complexity

In order to comprehend the challenges in Systems biology, it is important to understand the origin of the complexity encountered in nature. First, it is important to note that complexity within a system does not necessarily come about as a consequence of the number of component parts. In physics, the macroscopic state or the dynamics of objects are oftentimes well described by a few parameters or simple mathematical equations. For example, the temperature of an object comes about due to the thermal agitation of its individual atoms. However, their average energy can be ascribed to a single, macroscopically measurable quantity.

A complex system is one in which the laws that describe its behavior are qualitatively different from those that govern its units, such that new features emerge as one moves from one temporal, spatial, or organizational scale to another. The science of complexity is about revealing the principles that govern the ways in which these new properties appear. Thus, it is rather the organization of the system into irreducible, heterogeneous parts that are highly structured and hierarchically organized on various spatiotemporal scales, which makes a system to become complex, or in other words, ''complicated.''

The notion of complexity is not well defined amongst the various science disciplines. Information theory usually characterizes complexity as the amount of information needed to optimally predict the behavior (or state) of the system on the basis of entropy measures. However, this definition refers to sequence complexity and is thus unsuitable for biology, where, for example, the sequential makeup of proteins is largely uncorrelated with their respective function. One viable approach toward defining the complexity of biological systems may be the identification of the topological structure at a higher level of large-scale organization in terms of hierarchically organized networks.

Complex systems in physics are usually defined to consist of many individual, yet simple, and identical or similar elements, whose complex dynamics arise from the interaction of its elements alone. Physicists try to deduce simple and few interaction laws, which are then sufficient to describe the complexity emerging at the macroscopic scale of a system, for example, by a power-law behavior with respect to the size of events and their probability to occur.

Different approaches toward describing this type of complex systems exist. One is the so-called ''slaving-principle''. It makes use of the fact that under certain conditions the global, macroscopic behavior of a system is governed by a few, slowly evolving state variables, which ''slave'' all other dynamics. This way, the relevant degrees of freedom of such a complex system are largely reduced, allowing the system to find its own structure, that is, to self-organize. One use of the slaving principle is the analytical description of lasers, explaining the spontaneous, synchronous light emission by the atoms in the lasing medium.

Another popular framework from statistical physics for the explanation of emergent phenomena in multibody systems is the notion of self-organized criticality (SOC), which was acclaimed to explain the frequent occurrence of long-tail distributions in many natural phenomena. SOC denotes the ability of open and dissipative

systems to display critical, that is, scale-invariant, behavior even in the absence of external pressures. Unfortunately, this theory did not live up to its promise of being universally applicable, but it has its applications in, for example, earthquake, forest fire, or avalanche models.

The limited applicability of SOC or the slaving principle on biological phenomena is mainly due to the fact that biological systems need a redefinition of complexity that is quite different from that in physics. Biological systems are heterogeneous, modular, highly structured on multiple irreducible spatiotemporal scales, and self-dissimilar with each entity usually having several functional and regulatory properties. Nevertheless, the individual components ''interact selectively and nonlinearly to produce coherent rather than complex behavior.''

Carlson and Doyle therefore introduced the theory of highly optimized tolerance (HOT). It accounts for the intrinsic design of biological and engineered systems. Their theory reflects the behavior of such high-throughput, high-density systems, which are faced with limited resources. These systems show a high tolerance, that is, robustness, against environmental parameter fluctuations. This robustness is achieved at the cost of a high degree of complexity through the addition of control units to the system. Resource constraints then call for an optimized tradeoff between fault tolerance toward frequently experienced perturbations and fragility to rare, yet possible events. Thus, there exists a ''conservation law of robustness.''

The complex design of even the simplest eukaryotic cells is often compared to the makeup of computers or today's commercial aircraft. Indeed, those man-made machines have a bewildering complexity such that no man alone understands all the parts and their interplay in complete detail. Many of the strongly interacting and irreducible complex functions are there to automate, control, or backup operations. This elucidates the main difference between systems describable by SOC or HOT. The former theory relates to scale-invariant and self-similar features, while the latter deals with self-dissimilar structures and sensitivities (dis-)appearing on each scale of observation such that the degrees of freedom in these systems are irreducibly many.

3.2 Global Properties of Biological Systems

Systems thinking provides universal properties of biological systems that link the emergence of complexity to other general design features. These can be used as a guideline for abstract mathematical modeling, looking for principles that are commonly shared between diverse species. Moreover, these properties show how biology and engineering converge on a systems level view.

3.2.1 Robustness of Biological Systems

Fault tolerance or robustness of biological systems denotes the maintenance of specific system functionalities even in the presence of fluctuations or a change in environmental parameters. In biology, it refers to the concept of homeostasis and the stability of developmental control. Robustness is achieved through the incorporation of regulatory control loops into a system, thus shielding or buffering the desired system functionality from environmental influence. Hence, it is important to note that robustness is a relative system property. For the maintenance of a certain equilibrium, other properties must evolve

and adapt. It is therefore required to define which cellular functions change and which resist as a reaction toward a disturbance.

Most of the ''complicatedness'' encountered in biological systems is a direct consequence of the implementation of control schemes rather than the core function itself. In particular, if robustness is to be achieved for a wide range of disturbances, the control must have an equally increasing variety as stated in the ''Law of Requisite Variety.'' Consequently, complexity serves simplicity in the sense that the complicated control schemes are hidden underneath the simple, yet reliable output.

Robustness in biological systems is usually achieved by redundant or functionally overlapping regulatory pathways, signal control with the help of feedback loops and certain checkpoints within the cell, all of which add to the total number of components regulating the cell, while keeping the number of distinct phenotypic characteristics low. Cellular checkpoints play an important role, for example, in mitosis, the cell cycle, and in the early stages of embryo development. Bacterial chemotaxis is an intensively studied example of a robust behavior due to multiple feedback control. An example for the use of genetic buffering for robustness is shown by the fact that only about 20% of genes in budding yeast are essential for viability.

Most biological systems employ complexity to buffer against environmental changes or genetic defects. For example, the simplest bacteria such as Mycoplasma with a couple of hundred genes survive only within a narrow band of environmental parameters. *Escherichia coli* on the other hand, possessing about 3000 genes, survive in various environmental conditions. Hence, most of the additional control schemes are inactive under normal laboratory conditions and are possibly activated under severe environmental conditions only, which usually hides the complexity of regulation.

Another interesting consequence of robustness comes from the assumption that dynamical behavior in biological systems is coupled less to parameters themselves, but more to the overall system structure itself. Von Dassow showed that robustness was the simplifying criterion for the determination of the correct topology of the segment polarity network, producing highly robust patterning over a large range of parameter variation.

Robustness in complex systems comes at the price of some fragility due to tiny, yet rare events. Indeed, a small rearrangement of some cellular signal pathways can oftentimes lead to a spectacular failure, that is, impaired cell death. For example, cancer can be caused through the accumulation of tiny mutations in the genetic code over the human life span. Nevertheless, the outbreak of cancer during the reproductive years of a human are rather rare and nature seems to cope well with this tradeoff for the benefit of robust and reliable ''normal'' functioning.

3.2.2 System Adaptation and Control

Adaptation is the ability of a system to accommodate for varying external input stimuli or disturbances to gain and maintain the correct and optimized output. This is usually achieved with the help of feedback control. Popular examples of adaptation using integral feedback control is chemotaxis, in which bacteria adapt their movement not to the absolute level of pheromones but to the chemical gradient only, or the activation of the heat shock protein in *E. coli* under temperature stress.

Control is a recurrent design encountered in natural systems, which effectively increases robustness with the goal to keep certain values within predefined physiological limits. One distinguishes between feedforward and feedback system control. The former is an open-loop sequence of predefined actions triggered by a certain stimulus, working reliably only within strict ranges of input stimuli, yet simple in design. The latter employs a closed-loop design, which feeds part of the output signal back into the system input. Depending on the sign of the feedback, positive feedback (or autocatalysis) will amplify the output signal, thus enhancing reliable sensitivity toward cellular decision derived from noisy input signals. Negative feedback, homeostasis, stabilizes the output around some desired value by opposing any changes caused by disturbances.

Although both types of control are successfully employed in intracellular signaling, both bear fragility as well. Autocatalysis can lead to self-sustained, unrestricted signal amplification, as observed in uncontrolled tumor growth, while ultrastable homeostasis regulation can cause large, possibly disturbing, transient signals in response to external fluctuations.

Most often, biological systems use combinations of open and closed-loop designs, basing their control action upon the absolute, accumulative, or differential value of the input stimulus, thus balancing both sensitivity and stability.

3.2.3 Modules and Protocols

Modules are characterized by being mostly self-contained, having fixed interfaces for external communication and are evolutionarily detached, possessing their own identity, having many internal, but only few external links through which information and matter is exchanged. Systems are then thought of as assemblies of modules, like entire living organisms or an individual.

Modular design is a commonly found principle in modern engineering. It enables the independent development and testing of units before integration into a common system. Further benefits are the savings in developmental and maintenance cost and the prospect of graceful degradation instead of catastrophic failure, as errors are usually restricted to a single module.

Similarly, modularity seems to be an important concept in biology, probably stemming from the evolutionary pressure for optimal flexibility and the low chance of damage spread. Spatially distinct entities, like organelles in the cell or metabolic units seem to be a recurrent scheme found throughout various organisms. Genomic research on the gene regulatory network of yeast led to the discovery of a set of regulatory motifs, which can be seen as conceptual modular entities. Such motifs have also been discovered in *E. coli* and are not unique to cellular regulation, emerging in food webs, the Internet and neural networks as well.

If modular design of biological systems is a governing principle, it opens up new possibilities for simplification of *in vivo* and *in silico* experiments. Modules would provide fixed levels of detail and size, which are easily abstracted once their functions are known. With the help of these core modules, it would be possible to build ever more complex models without the need for segmentation of every level of detail.

Modules communicate using protocols. Protocols are fixed, commonly agreed on rules that standardize communication with their respective surroundings. They ensure error correction, cellular coordination, as well as evolvability through the

possibility of adding new functions to a particular module. It has been shown that protocols are an efficient means for the hierarchical organization of complex systems through their integration of different layers, thus reducing the costs of information transmission. For example, negative feedback is a powerful module for the establishment of homeostasis. Similarly, gene regulation, membrane potentials, or signal transduction pathways can all be regarded as protocols being utilized by the different biological modules, such as the DNA, ion channels or kinases, and phosphatases. Elaborate feedback control protocols are robustly established for the spatiotemporal development of various species. An extensive genome-wide analysis of prokaryotic cell-cycle progression revealed a hierarchical control structure with three to four master regulatory proteins acting in a coordinated fashion.

Interestingly, the use of protocols on the cellular level has striking similarities with modern communication of computers via the Internet. The Internet employs many protocols for persistent communication, which can be ordered into a general hierarchy starting from the data link via the network and transport to the application layer. Popular examples of each hierarchy are the reverse address resolution protocol (RARP) for the IP lookup and search of the communication partner, IP for routing for the appropriate subnet of the data, TCP for the secure, error-free data exchange, and finally the application layer like HTTP or FTP for retrieving a Web page or downloading files. The fact that these protocols have been used for decades, irrespective of the fast and ongoing evolution of computer hard- and software, highlights their importance. The Internet moved into the focus of intensive research, beginning to have a rich theory. Its close resemblance with other complex systems, while at the same time having available enormous data sets, make it an attractive example to compare with biological networks.

4 Systems Biology Modeling

The word model derives from the Latin language ''modus,'' that is, ''manner, measure,'' and refers to the concept of representing causal relationships from real systems in the language of mathematics. This mapping oftentimes involves simplifications of the original systems with the hope to gain predictive powers on experimental results and to explain functional design principles.

Modeling and simulation have become indispensable tools for gaining insights into natural systems. In biology, they help to bridge the gap between theory and experiment. Oftentimes, the biologists are faced with the dilemma that experiments do not provide sufficient data for theoretical interpretation, while at the same time, clues for new experiments are missing as a consequence of lacking hypotheses.

Experimental results need proper mathematical interpretation and model hypotheses require experimental proofs. Thus, the process of knowledge generation is an iterative process consisting of two feedback loops (Fig. 1). The experimental part employs experimental techniques to obtain quantitative data of the system dynamics. These are then compared with predictions by the mathematical model. In the case of failure, that is, in the case of diverging results from model and experiment, this process must be repeated by

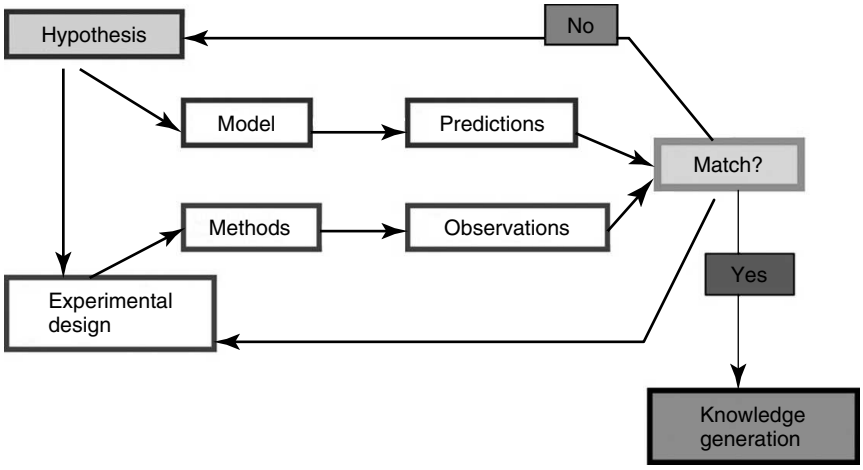

Fig. 1 Schematic to the experiment-modeling loop for knowledge generation in Systems biology.

adjusting the old hypothesis and thus reconciling the model with the new results from the experiment. As an example of this cycle of model building, experiment, and model refinement, Ideker et al. recently developed an integrated approach to construct, test, confirm, and refine the simulation of the yeast galactose utilization network through the combined numerical simulation and analysis of networks with systematic experimental perturbation and global measurements.

The major guideline for optimal modeling should be the concept of Occam's razor, which states that models should be void of any redundant information. In the times of modern biology, this paradigm also needs to be viewed from the other side, that is, that models must not be oversimplified, and thus missing the essential clues of functionality of real-life systems. In particular, it is important to note that modeling in biology must establish different concepts than those in physics. The paradigm of nonlinear science is that even simple systems can lead to dynamically rich behavior. Despite the beauty of the simplicity of this idea, one must realize, however, that living systems regulate their dynamics differently, that is, through a complex makeup of interconnected regulatory functions, a fact that is often neglected or ignored.

Models in biology are usually heuristic. They arise embedded in the process of biological experiments and are coupled tightly to them. Information is, for example, deduced from perturbation analysis of the experimental system and thus contains assumptions about the causality and the passage of time. The construction of a valid working model of a biological system from experimental data can be approached from two sides.

The bottom-up modeling of cellular functions is based on the integration of established biological knowledge on the dynamics of the relevant biological components of the system or regulatory network under consideration. This attempt is useful, when most of the reaction partners are known and their interaction dynamics are understood. The research goal is the establishment of an accurate computer simulation that allows for (1) the analysis

of the system dynamics (2) the scan of parameter ranges that are unattainable in experiments (3) the prediction of unknown functionality or interactions. Attempts of a bottom-up modeling are, for example, the λ-phage decision circuit or the data-driven simulation of a cancer cell.

The top-down modeling ansatz tries to apply statistical analysis to data from high-throughput experiments coming, for example, from DNA microarrays. Data mining techniques search for clusters of coexpressed genes as a consequence of an external perturbation, like the knockout or overexpression of certain genes. The working assumption for these methods is that coexpressed genes also share common relationships with respect to other biological processes, for example, metabolic pathways. The result of a cluster analysis is the construction of an interaction network of genes or proteins, whose topology can hint at biologically reasonable organization principles.

The knowledge-based bottom-up approaches toward modeling possess a certain appeal to biologists. However, successful modeling needs to overcome the gaps in understanding. Most of protein–protein interactions are still unknown and the underlying physics of interacting molecules needs better attention. The influence of high molecule concentration in subcompartments of a cell environment on reaction rates is as yet widely unknown. The spatial distribution of reactants and molecular crowding may well affect reactions and their rates, for example, explaining the symmetry breaking process of mitosis. A particular challenge arises from identifying the relevant components, which is most difficult due to the vast number of combinations of active molecules. These obstacles presently impair mathematical modeling in biology.

Besides the ever growing need for more experimental biological data, the success of quantitative modeling will especially depend on the quality and diversity of such data. Experimental data needs to be comprehensive with respect to four aspects:

Factor: the need to capture the behavior of all important target factors, such as the genes and proteins that play decisive roles in the experimental system under consideration.

Item: this refers to the simultaneous measuring of necessary sets of variables, such as transcription level, molecule concentration or spatial information that are required for reliable hypothesis building from experiments.

Time and space: this refers to the need for a sufficiently high spatiotemporal sampling rate of the experimental data to obtain a reasonable resolution of the spatiotemporal dynamics.

Repetition: experiments need to be repeated in a reliable fashion to obtain a statistically reliable estimate for the biological variability of the system and other sources of error induced by the experimental setup.

In particular, the last aspect is often neglected in biology both in terms of the necessary number of experiment repetitions, as well as the false integration of data from inconsistent samples. This can lead, for example, to many false-positive or false-negative results in public genomic databases.

Regardless of the approach, one needs to define the level of model abstraction, complexity, and spatiotemporal scale of the system under investigation. The level of

abstraction leads to certain dynamics being modeled and simulated in detail, while for other parts, the details can be neglected, for example, due to low sensitivity toward specific parameter values, or considered as black boxes characterized by their input/output behavior.

The major goal of theory and model simulations is reverse engineering of biological systems, which is ''the process of analyzing a system to identify its components and their interrelationships and create representations of the system in another form or at a higher level of abstraction.'' However, biological systems pose a major challenge toward reverse engineering due to the hidden complexities, inherent robustness, and possibly suboptimal design of functional units. Circular causality makes it hard to distinguish between cause and effect from biological data. All of this imposes ambiguities so as to deduce the correct biological ''wiring diagram'' from the experimental data. It is the hope that systems thinking in biology with its concepts of robustness, hierarchy and modularity, and protocols will provide detailed bottom-up models with testable hypotheses for model discrimination.

Different tools are available for the translation of experimental data into the language of mathematics, whose use depends on the degree of model abstraction and the spatiotemporal resolution of the system under consideration. In the following, we will focus on the motivation of network biology, as an example of system-level dissection of biological systems from an organizational point of view.

4.1 Network Biology

Network biology attempts to deduce the internal organization of a biological system from its organizational network topology that can be understood easily with relatively few and simple mathematical rules. It is hoped that fundamental relationships will emerge from essentially statistical analyses of large genomic and proteomics databases through this system-level approach.

Graph theoretic concepts have long since been used by biologists to visualize the interactions of genes, proteins, and metabolites. Such graphs consist of a set of nodes forming an interaction network. Usually, the nodes stand for the state variables of the system, like molecule concentrations, while the connections define the dynamics, that is, the type of interaction between them. Emergent phenomena then arise from the interplay of local and global dynamics due to the nodes and connections, respectively.

Networks are characterized by the connectivity, path length, and clustering distributions. Connectivity tells how many neighbors each node has on average. The path length denotes the average separation between arbitrarily chosen nodes, and the clustering coefficient is a measure of the grouping tendency of the nodes. Apart from these network measures, it is important to investigate the network architecture. Depending on the way the various nodes organize themselves into a network, different final network topologies appear.

Random networks appear by randomly connecting pairs out of a fixed set of nodes. It can be shown that the connectivity distribution follows a Poisson statistic, while the mean path length increases proportional to $\log N$, where N is the number of nodes. This type of network shows a small-world effect: any two nodes can be connected with just a few links.

Scale-free networks possess few highly connected nodes, called *hubs*, while many

nodes share only few connections. Hence, the connectivity distribution follows a power-law, that is, $P(k) \propto k^{-\gamma}$, where k and $P(k)$ denote the connectivity and distribution, respectively, and γ is the connectivity exponent. Such networks appear, if new nodes have a preferential attachment to already highly connected hubs. They possess ultrashort path lengths proportional to log log N.

Scale-free hierarchical networks are constructed out of a growth process, which iteratively replicates and loosely connects clusters or highly connected nodes, while also establishing links to clusters of previous grow steps. These rules assure a hierarchical structure of ever-smaller clusters down to an original seeding cluster.

High-throughput data collection has empowered the biological community to draw ever more detailed interaction webs of protein–protein, metabolite and gene transcription networks. Network biology relates to the field that attempts to discover universal design and organization principles, which govern the functioning and evolution of inner- and intracell networks. It has been discovered recently that all biological networks share certain topologies best described by scale-free networks, usually having exponents of $2 < \gamma < 3$. Interestingly, this type of complex network also emerges in other aspects of life and society, such as the World Wide Web and social interaction webs. Moreover, metabolic networks in the cell seem to share the property of ultrasmall world effects.

First experimental results on yeast and *E. coli* seem to support the view that metabolic as well as genomic regulatory networks show a hierarchical organization with few recurrent subnetworks called *motifs* that hint at the existence of elementary regulatory units. While modules are discrete functional units that are semi-detached from the whole system, motifs comprise a set of genes or metabolites that form recurring, significant patterns of interconnections, inseparable from the rest of the system. Ravasz et al. showed that the metabolic networks of 43 distinct organisms have a modular organization interconnected in a hierarchical manner – a system-level cellular organization that might be generic in nature.

The true reason for the preferred occurrence of scale-free networks in nature still remains elusive. Yet, there are a few possible explanations. Scale-free networks come about due to growth with preferred attachment. Considering the evolutionary history of metabolic networks, they might have grown through the addition of ever more metabolites to highly connected nodes already present in the system. Scale-free networks are also preferable with respect to functional robustness. Randomly deleting nodes from the network will most likely hit a loosely connected node, while there is a low probability that one deletes a hub.

The need to investigate the interconnections of genes–proteins and proteins–proteins stems from the fact that the genome of various species is quite similar, whereas it has been argued that the evolution of ever more complex species is correlated with an increased functional connectivity between a constant number of genes. Motifs might provide a way to increase interconnectivity of existing proteins, this way creating new functionalities. ''This is likely one of several reasons that the apparent complexity of organisms can increase so markedly without a corresponding increase in gene number. An attribute of proteins encoded by the human genome is that they have a richer assembly of domains than do their counterparts

in invertebrates or yeast, and indeed the assortment of domains into novel combinations is likely an important aspect of genome divergence.''

Usually, only an incomplete knowledge about the system under investigation is available. In these cases, Bayesian networks can ameliorate the insufficient knowledge by modeling the known and unknown interactions in a directed, probabilistic cause–effect graph. The Bayes' rules then allow the researcher to combine new hypotheses with the existing knowledge from experiment. Likewise, the Bayesian networks allow to induce those network structures that best match the known expression data of a given regulatory network.

From the success of network biology, Oltvai and Barabasi propose to view the organization of cellular function in terms of a complexity pyramid. Accordingly, cellular functions are separated into groups of heterogeneous components and function, all interacting within large networks. Each higher functional cellular level, starting from molecular components like DNA to metabolic pathways, functional modules to large-scale network organization, is ever more universally applicable to a multitude of species. This way, network biology provides a new view on the organizational structure, behavior, and function of the cell. It similarly bestows new approaches of bottom-up and top-down modeling, that is, moving from molecules to motifs and modules, or starting from the other end with the construction of scale-free, hierarchical networks and then including organism-specific modules and motifs. Altogether, this global organization seems to be a hint for an evolutionary family of circuits with recurring dynamic organizational principles, which opens up the possibility of establishing ''a periodic table for functional regulatory circuits.''

4.1.1 Dynamic Network Models

Despite the intuitive appeal of network biology toward the structure identification of biological systems, it is limited in the sense that it does not include the temporal dynamics of the system. Boolean networks are an abstract, yet viable, approach toward the inclusion of a temporal evolution of large-scale networks, while at the same time being easy to handle both analytically and numerically. Each node can assume an ON/OFF value. Then, the state of each node at the next time step $(t + 1)$ is deduced deterministically from a logical Boolean function, that is, *AND*, *OR*, *NAND*. . ., based on its current state and external input. While Boolean networks have been successfully used for the analysis of gene regulatory networks, they completely neglect the continuous nature of concentration gradients or stochastic effects. The inclusion of these into model simulations is the topic of the following sections.

4.2 Reaction-diffusion Models

Differential equations provide a mathematical description of system dynamics with continuous system states in time and space. They are the most widespread formalism to model systems throughout the various scientific domains, having a long history of more than 300 years. In biology, they are widely used to describe the time and space course of molecular concentrations with the interaction between the various reactants being modeled through functional and differential relations. There is a vast literature available on modeling

biochemical reactions based on differential equations, especially in the context of metabolic processes.

In general, one distinguishes between purely time-dependent ordinary differential equations (ODE), and more general partial differential equations (PDE), which additionally include spatial dimensions. A PDE describing the spatiotemporal evolution of a system has the general form

$$\frac{\partial \psi_i(\mathbf{r}, t)}{\partial t} = \underbrace{f[\psi_i(\mathbf{r}, t)]}_{\text{temporal evolution}} + \underbrace{\nabla \mathbf{D_i}(\mathbf{r}, t) \nabla \psi_i(\mathbf{r}, t)}_{\text{spatial Diffusion}}, \quad (1)$$

where $\psi_i(\mathbf{r}, t)$ denotes the respective system state variables of the various molecules labeled by the subscript i. The above equation reduces to an ODE in the absence of spatial diffusion, which is $\mathbf{D}(\mathbf{r}, t) = 0$. The term $f[\psi_i(\mathbf{r}, t)]$ denotes the respective synthesis rates, depending on the various concentrations of $\psi_i(\mathbf{r}, t)$ and possibly external signals. It is often composed of the various, mostly nonlinear, interaction functions between the system metabolites based on the "law of mass action" of metabolic processes, for example, Michaelis–Menten-like enzymatic degradation, inhibition of the Hill type.

The spatial aspect of the equation enters the description due to the inclusion of a diffusion term, where the diffusion term $\mathbf{D_i}(\mathbf{r}, t)$ depends on space and time in general. Alan Turing was the first to point out such reaction-diffusion systems as a possible explanation for morphogenesis in natural systems. He showed theoretically that a system of reacting and diffusing chemicals can evolve spontaneously to a spatially heterogeneous state as a response to an infinitesimally small forcing. This pioneering work led to a new branch of research and many so-called Turing systems have been proposed (however, not finally been proven) to account for pattern formation in developmental biology, for example, explaining the pattern formation on snail houses, modeling Drosophila embryogenesis, or explaining the coating patterns of animals.

The importance of spatiotemporal inhomogeneities in molecular concentrations and molecular crowding in signal transduction pathways has recently been acknowledged. As a consequence, cellular functions also employ on active transport mechanisms to sustain reliable cellular processes.

Owing to the nonlinear interaction terms $f[\psi_i(\mathbf{r}, t)]$, an analytical solution of the differential equation is possible in rare cases, only. However, a stability analysis is always feasible and gives a good insight into the qualitative behavior of the local stability of the steady state solutions and the occurrence of periodic solutions in space and time.

In these cases, a quantitative insight into the respective equations can be obtained from numerical simulations. A variety of numerical integration algorithms can be found in standard literature; moreover, several computer software packages have been developed specifically for the simulation and bifurcation analysis of nonlinear systems, such as GEPASI or DBSolve.

4.3 Intracellular Noise Models

The above approach of differential equations for the mechanistic description of biological phenomena implicitly relies on the "law of mass action." This law relates the molecular component concentrations to reaction rates. It is valid in homogeneous, well-mixed environment, assuming the underlying reactions to be continuous

and deterministic. Under these prerequisites, the complete time-course of the reactions is determined by the initial conditions.

Deducing effective reaction rates from molecular interactions fails in the case of low particle numbers. There, the discrete and random nature of the individual, elementary reactions between molecules inevitably comes forth, showing its impact on a macroscopic scale as fluctuations in the molecule concentration over time. In molecular biology, this intrinsic noise becomes most significant in the regulation of gene expression, as it is usually accompanied with low copy numbers of mRNA transcripts and the genes themselves. Stochastic effects are attributed to be the cause of phenotypic diversity in isogenetic populations of cells. They play a major role in the lysis-lysogeny decision circle of the λ-phage and are shown to be a decisive element in the threshold behavior of CD95-induced apoptosis.

Nature both exploits and copes with noise. Regulatory determinism of gene expression and thus reduction of noise is achieved by redundant gene configurations, highly improving the regulation reliability. Another strategy is the embedding of the respective gene function into a pool of many ''background'' reaction partners.

At the same time, there exists a ''positive'' effect of noise in biological systems. Noise-induced phenotypic diversity increases the likelihood of species survival within a wider range of environmental parameters and allows for a more rapid evolutionary adaptation to environmental pressure. The constructive and ordering role of noise in terms of information transfer is long since known from the phenomenon of Stochastic Resonance (SR). Experiments have shown that neurons increase their sensitivity toward weak input signal through the addition of ambient noise. Likewise, Paulsson et al. theoretically deduced an effect called *stochastic focusing*. Cellular mechanisms might show an increased sensitivity toward input signals as a result of additional noise-induced degrees of freedom.

The analytical treatment of stochasticity in chemical reactions starts from defining a joint probability distribution $p(\mathbf{X}, t)$ of the system, where $\mathbf{X} = [X_1, \ldots, X_n]$ denotes a discrete number of n different molecule types at time t. The temporal evolution of p is described by a master equation, which is a gain–loss equation for the probabilities of the separate states $\mathbf{X}$

$$\frac{\partial p(\mathbf{X}, t)}{\partial t} = \sum_{j=1}^{m} \left(\beta_j - \alpha_j p(\mathbf{X}, t)\right), \qquad (2)$$

where m different elementary reactions are considered with $\alpha_j \Delta t$ and $\beta_j \Delta t$ denoting the loss and gain terms, respectively. The former are the probabilities that some reaction j occurs within the time interval $[t, t + \Delta t]$, while the latter is the gain due to transitions from other states to $p(\mathbf{X}, t)$. Albeit the intuitive simplicity of the master equation approach, its analytical solution is mostly impossible and even its numerical manageability is limited.

An alternative to the evaluation of the master equation is the stochastic simulation algorithm (SSA), which is the numerical approximation to the microscopic behavior of reacting chemicals in a ''well-mixed'' environment. The algorithm randomly chooses the reaction type and the integration step size on the basis of the current rate constants and population size of the chemical reactants. The relative probabilities for each elementary reaction

are derived from the respective propensity functions, which relate the reaction probability to the possible molecule combinations and their effective reaction speeds. One simulation run then consists of iteratively calculating the probability density according to the propensity functions, updating the integration time and chemical populations with respect to the randomly chosen step size and reaction stoichiometry, respectively. It can be shown that the SSA leads to the correct master equation representation, such that the average of many SSA realizations converge to the correct probability density $p(\mathbf{X}, t)$.

No matter how useful the SSA algorithm is, it has a main limitation stemming from the need for detailed knowledge about every single reaction mechanism as well as the requirement for only one reaction to take place within a given time interval, which can be very small indeed. Furthermore, several simulation runs need to be performed in order to obtain valid averages of the probability density $p(\mathbf{X}, t)$. These conditions render the algorithm computationally demanding, especially in the case of large numbers of molecule species. Therefore, various refinements have been proposed for the above algorithm that either aim at reducing the number of calculations at each integration step or increasing the time step size by allowing several reactions to take place at once.

Stochastic modeling converges to the ''Law of Mass Action'' in the case of large molecule numbers, where the fluctuation reaction probabilities can be replaced by effective kinetic parameters. In between, there exists an intermediate range, however, in which the discrete structure of reaction events becomes insignificant, yet the stochastic effects still prevail on the macroscopic scale. Then, the dynamics become quasi time-continuous and can be described by a stochastic differential equation (SDE), called *chemical Langevin equation*, that is, an ordinary differential equation with an additional noise term. While the numerical simulation of SDEs is mathematically well established, uncertainties persist concerning the validity range of this approximation as well as statistical representation of the ad hoc noise term added to the equations.

To reduce the computational complexity of stochastic simulation, hybrid simulation systems have been proposed recently. Noting the fact that molecule numbers in the cell can vary substantially over time, it is possible to simply apply efficient ODEs or SDEs for system integration at times of large and intermediate molecule numbers, while switching to discrete stochastic simulation, for molecules with a number below a certain threshold. This way, the crucial effects of stochasticity at low particle numbers are conserved while maintaining acceptable losses in accuracy.

4.4 Modeling Resources

The development of a standardized computer infrastructure is of utmost importance to manage the increasing amount of knowledge on biological systems. This helps the effective utilization of resources and the exchange of models, ideas, and data. An integrative software tool for Systems biology should comprise the following features for proper systems understanding. From a mathematical point of view, such tools need support for different simulation algorithms, such as deterministic and stochastic ordinary and partial differential equation solver and should include analysis algorithms for parameter estimation and model discrimination. From an experimental point of view, it

should have support for a standardized modeling language. In terms of software, the simulation package should run independently from the computer platform and preferably on a computer grid or cluster environment.

A number of simulation packages are currently under active development, most of them freely available. As a consequence of the complexity encountered in biological systems, there is no integrative software package, capable of handling all phenomena in signal transduction, metabolic pathways, or spatiotemporal simulations. Some of the currently most versatile packages among many are ECell, Virtual Cell, or Cellware. Simulation packages for truly spatiotemporal simulation of biological systems are currently under active development.

Model building is a complex enterprise and is usually accomplished in collaboration with scientists from different research institutions. Serving the need for seamless information exchange of computer-based models, common standard markup languages based on the XML format are currently developed. The most popular ones are CellML, BioPAX, and SBML. The Systems biology workbench extends the above approach by providing a standardized application interface for researchers to not only exchange model data and results but also the simulation tools themselves.

Another great challenge lies in the inherent modeling of stochasticity of inner cell processes. The SSA algorithm from Gillespie is computationally infeasible with an increasing number of molecules, and the computational power for exact stochastic simulations will be immense. Therefore, different algorithms have been developed, like reducing the number of random variables for simulation or allowing to take larger integration time steps at a justifiable error in the respective reaction probabilities. Several program packages for the simulation of stochastic molecular dynamics exist, for example, StochSim or Stocks. Programs like SmartCell tackle the simulation of spatially extended stochastic systems.

Regardless of the modeling approach of biological systems there is always the need for parameter estimates of at least a few constituents of the model. Because of the sheer amount of parameters required for successful modeling on one hand and the huge number of experiments already performed, the need to organize experimental data has brought about several publicly available databases of molecular properties, interactions, and pathways. They provide an invaluable infrastructure for future modeling efforts, enabling the modeler to start simulations from a certain degree of abstraction.

Spatiotemporal modeling will additionally require information about the physical structure of its model constituents as obtained from microscopy. For these needs, the development of an Open Microscope Environment, which is currently being built as a joint effort amongst various research institutions, will provide a unified data format and database environment for consistently annotating, storing, and retrieving five dimensional microscope images (four dimensions in space and time with additional color information) and exchanging them between research institutions.

5 Future Prospects of Systems Biology

The systematic synthesis of experimental data into model descriptions nourishes the

hope that biology will one day become a branch of science close to engineering. Once the biologists have learned the "language of the genes," that is, their syntax and their semantics, they will have the theoretical background knowledge and the experimental expertise to draft and create synthetic model cells or even organisms from scratch, on which new drugs and cures can be tested *in silico* before a possible assembly *in vivo*.

The impact of Systems biology will change medical practice. With the advent of functional understanding of living systems, it will be possible to devise new anticancer therapies that first identify the particularities of heterogeneous tumor cell populations and then try to predict and control cell activity to detect and use specific fragile points of each tumor cell type. The current problem with chemotherapy is the multidrug resistance of most tumor cells as well as the drugs' mutagenic property. They kill part of the cancer population, while fostering the diversification of other cancer cell strains. Thus, viewing cancer from a systemic level as a robust system instead might provide physicians with a framework for future anticancer strategies.

5.1 Synthetic Cell Biology

Currently, genetic engineering of organisms is mostly done by inserting genes into the DNA of plants and animals, yet the ultimate goal will be the design of living matter from scratch. Arkin claims that molecular biology has entered a stage of maturity that requires its transformation into an engineering discipline. Synthetic biology is a future vision for coming decades based on the current progress in cellular, molecular biology as well as genetics and associated fields of engineering and computer science. With synthetic biology being the technological counterpart of Systems biology, it is the hope that their combined knowledge will enable the creation of essentially artificial systems using biological design principles with new combinations of building modules from existing (sub)cellular systems.

Synthetic biology departs from a component-based approach. It views a living system as being composed of interacting modules, each having particular functions that exchange their information via protocols. Current research suggests that these modules are limited in number, albeit their specific tasks being diverse. Synthetic biology implies a scientific agenda on a higher level of abstraction toward identifying and categorizing the various module types within the cell and across organisms, investigating their interactions on the basis of the module, rather than molecule-interaction. From an engineering point of view, this means that modules can be taken out of their current evolutionary context and assembled differently in the sense of versatile building blocks.

As a first step, there are efforts to characterize the workings of switches, bi-stable systems or stabilizing control loops from simple chemical reaction schemes, in a systematic way. Different authors describe the fundamental principles of building logical circuits in the language of gene regulatory networks. Tyson et al. present a systematic overview of designs for biological control systems such as switches, sniffers, or buzzers, and combine the mathematical description with experimental findings. Hasty et al. review the possibilities for constructing gene circuits serving various functions such as autoregulation, repression or logical gates. In a first *de novo* design study of a gene regulatory network,

Guet et al. systematically analyzed the phenotypic behavior of different parameter and topology combinations in a genetic regulatory network. They constructed various logical gates, such as NAND, NOR, and NOT IF, through the combination of three nodes together with five promoters. As an important result, they found that both parameter values as well as network topology are important to unambiguously determine the systems' computational function.

A Biological Information System (BIS) is to be established in the long run, extending genomic databases with quantitative mechanistic knowledge. Using all data in an integrated form, it will be possible to build refined theories by checking on key molecules, replacing complex pathways with effective reaction parameters, and thus defining biologically meaningful reaction subsets from the large amount of possible reactions.

Kitano calls for the establishment of an international Systeome project (alluding to the joint efforts of the Human Genome Project), which aims at promoting Systems biology by creating such a comprehensive data resource of biological systems features. He defines this grand challenge as ''the assembly of system profiles for all generic variations and environmental stimuli responses.'' Several model organisms, like yeast, *Caenorhabditis elegans*, *Drosophila C.*, the mouse and finally the human shall serve as the ''rosetta stones'' for the establishment of a working *in silico* simulation model of life, whose establishment is hoped to be finished by the year 2030.

One further important aspect of Synthetic biology is the possible risk analysis of current and future artificial genetic mutations in plants and animals. At this point, nobody can assess the long-term risks of releasing new artificial gene pools into the wild. Erwin Chargaff, who pioneered our understanding of the DNA, took a rather pessimistic view on the disproportionate ratio between technological possibilities of genetic engineering and the knowledge about its implications:

> ''Bacteria and Viruses have always formed a most effective biological underground. The Guerilla warfare through which they act on higher forms of life is only imperfectly understood. By adding to this arsenal freakish forms of life – procaryotes propagating eukaryotic genes – we shall be throwing a veil of uncertainties over the life of coming generations. Have we the right to counteract, irreversibly, the evolutionary wisdom of millions of years, in order to satisfy the ambition and curiosity of a few scientists? [. . .] My generation, or perhaps the one preceding mine, has been the first to engage, under the leadership of the exact sciences, in a destructive colonial warfare against nature. The future will curse us for it.''

Albeit the above quote dates from 1976, it is still relevant, for example, with respect to the ongoing debate on the commercial use of genetically mutated crop. Chargaff's pessimism is not without foundation. Genetics has established the techniques for altering systematically the genetic makeup; however, a deeper understanding on the effects of manipulating so intricate a design as the cell cycle is still lacking. A Systeome project is thus the logical and necessary sequitur of the era of genomics. It will help clarify the consequences of gene transfer and inheritance in order to avoid potentially dangerous mutations.

5.2 Conclusions – Where are We?

The headline question of this section is easily answered: we are at the very beginning of a new branch of science. The road ahead is clearly marked and commonly agreed on

by many people. Yet, the trouble in all processes lies with the detail of things. The authors are not saying that the goals of Systems biology cannot be achieved, though its requirements are so outstanding that they call for drastic measures. This starts with the need for the scientists of different disciplines to learn a common scientific language as well as to have a definition of common goals.

To date, most experimental biosciences are method-driven, paying a lot of attention to details and produce, in extreme cases, loads of data out of context. Theoretical sciences on the other hand are principle-driven, neglecting important details, and thus coming up with theorems and models out of this world. As a consequence, all researchers will have to learn to focus on the important parts of their respective systems that are under investigation, yet varying which part to measure in detail and which part to neglect.

The biologists must adopt abstract thinking, trusting in the language of mathematics and necessary simplification. The physicists must learn to abolish oversimplified thinking and to get used to the analysis of strongly interacting systems with many degrees of freedom. Engineers must gain a deeper understanding of their systems under investigation beyond numerical solutions, for example, in terms of process optimization. The necessary unification of the various branches of science for the sake of the advancement of Systems biology will make communication skills among scientists ever more important. Years of ''isolated'' research have diversified the scientific vocabulary and methods, making it sometimes hard to mediate and discuss interdisciplinary goals and methods. Furthermore, scientists must learn to put their own research into the bigger frame of interdisciplinary research and research teams.

Despite this increased complexity of systems, there is still the need for an intuitive understanding of the relevant elements of the system under study. Complex computer models of biological systems lacking intuitive understanding can be regarded as an isomorphic mapping from one unknown system *in vivo* to another unknown system *in silico*. Unfortunately, despite a certain reliability factor in the agreement of experiment and simulation, it is impossible to finally prove the validity of such a model. For as long as there is a lack of complete understanding, there is always the possibility of new insights, which might render the current concept false. Vilar et al. even argue, using the example of the lac operon that ''even in the 'postgenomic era' [modeling] will still rely more on good intuition and skills of quantitative biologists than on the sheer power of computers.''

It is the strong belief that Systems biology will promote a unification of sciences, if the community is working ''holistically'' in a joint effort of biology, mathematics, physics, and engineering. Then, a new generation of scientists with an interdisciplinary training will emerge, whose everyday business will comprise working in the lab as well as performing data analysis and model simulations, exchanging data and results freely through publicly available databases. With the establishment of new experimental techniques and mathematical tools, asking the right questions, we can be sure that the systems approach to biology will be a great success. It will not only change modern life sciences but it will also change the view on life itself and finally we could prove the late Cassandra, Mr. Chargaff, wrong.

Keywords

Biomarker
A characteristic that is objectively measured and evaluated as an indicator or prognostic of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention.

Functional Informatics
Experimental paradigm based on the convergence and integration of bioinformatics and broad-based automation.

Targeted Therapy
Treatments directed toward inhibition or modulation of specific signaling pathways, receptors, or enzymatic cascades.

The concept of Targeted Therapy was developed over the past 10 years and it relies on inhibition of specific signaling pathways, as opposed to nonspecific chemotherapy. Consequently, if targeted pathways are differentially activated between normal and malignant cells, significantly fewer side effects would be expected in clinical settings. Translocations and other genomic changes that occur in malignancies lead to activation of specific signaling pathways and/or enzymatic cascades, which can be specifically and selectively addressed with therapeutic agents.

1 Principals of Targeted Therapy

1.1 Molecular Basis

Genetic instability is the hallmark of cancer as a disease. Gene alterations range from amplification, insertions, deletions, chromosomal translocations, or point mutations in the tumor cell's DNA. These genetic modifications lead to changes in tumor cell physiology, which can be specifically and selectively targeted by therapeutic agents. Inhibitors of cell cycle, growth factor signaling cascades, protein folding, angiogenesis, and apoptosis are among the main areas of focus for targeted therapy in oncology. The Cancer Genome Anatomy Project (CGAP) was created to provide a database of these genetic alterations in cancer genomes and is currently the most comprehensive freely accessible database to date (http://cgap.nci.nih.gov). Further, analysis that link these genetic changes with poorer prognosis afford the opportunity to create molecular road maps that may lead to a greater understanding of the processes that lead to uncontrolled cell growth.

1.2 Chromosomal Translocation

Oncogenes (genes that cause cellular transformation) can be activated as a result

of chromosomal translocation. The fusion protein, Bcr-Abl, occurs as a result of a chromosomal translocation between chromosome 9 and 22 (referred to as the *Philadelphia chromosome*) in white blood cells of about 95% of patients with chronic myelogenous leukemia (CML). The FDA approved Gleevec/Glivec (imatinib mesylate), an inhibitor of the Bcr-Abl tyrosine protein kinase, in 2001, as first-line treatment for newly diagnosed CML patients. A side-by-side comparison of Gleevec with interferon-α plus cytarabine revealed remarkable complete cytogenetic response rates of 76% in the group treated with Gleevec as compared to 15% in the group treated with interferon-α plus cytarabine. Whereas resistance to Gleevec therapy is rare (5–10%) in newly diagnosed patients in the early chronic phase of CML, it can occur in up to 60 to 70% of patients in the late blast phase, a stage at which the number of immature abnormal white blood cells in the marrow and blood are extremely high. This resistance, in part, occurs as a result of acquired mutations in Bcr-Abl that make inhibitor binding less effective. Such mutations that can occur over treatment time and the acquisition of other genetic changes support the continual development of therapeutics for this disease including less mutation-sensitive inhibitors of Bcr-Abl. Gleevec also inhibits other related kinases, such as the platelet derived growth factor receptor (PDGFR) and c-kit. As a result of positive clinical outcome in patients with c-kit positive gastrointestinal stromal tumors, it was also approved for this indication in 2002. Gleevec is currently being tested in over 40 clinical trials in combination with a wide variety of agents including other targeted therapies as well as standard chemotherapy.

1.3 Gene Amplification

Gene amplification resulting in the overexpression of proteins that are critical in growth factor stimulated signaling pathways are also targets of potential therapy. Examples of this are inhibitors that block the epidermal growth factor receptor (EGFR). EGFR is overexpressed and associated with poor prognosis in a wide variety of tumors such as lung, gastrointestinal, pancreatic, and colorectal. There are currently three approved therapies that directly inhibit EGFR: Iressa (Gefitnib) for the treatment of non-small cell lung carcinoma (NSCLC), Erbitux (Cetuximab) for treating colorectal cancer and Tarceva (Irlotinib) for NSCLC. Clinical trials with Iressa revealed a relatively low 10% response rate and the response did not appear to correlate with EGFR overexpression. Retrospective analysis of responders revealed that the response was selective for a patient population with activating mutations in the receptor. These results underscore the need to understand how the targets are driving tumor growth and highlight the need for prescreening patients to identify those patient populations who are most likely to respond to the therapy. Another member of the tyrosine kinase EGFR family, HER2 or EGFR2, is overexpressed in breast tumors and is the target of an antibody therapeutic called *Herceptin* (Trastuzumab) that was approved in 1998 for the treatment of metastatic breast cancer.

1.4 Tumor-specific Receptor Expression

Arguably, the first targeted therapy approved by the FDA occurred over 20 years

ago and acts as a weakly binding estrogen mimetic that competes with endogenous estrogen and effectively blocks the activity of the estrogen receptor found on breast tumors. Nolvadex (Tamoxifen) was first approved for use in the treatment of estrogen receptor positive breast cancer. In 1998, Nolvadex gained a new indication when it was demonstrated in a National Cancer Institute funded study, that it reduced the incidence of developing breast cancer by 44% in women considered at high risk for developing the disease. However, a small risk factor of endometrial cancer has been associated with long-term use of Nolvadex in postmenopausal women. This risk factor potentially may be circumvented by a novel antiestrogen, Faslodex (Fulvestrant), that is a more potent estrogen receptor antagonist than Nolvadex and has been shown to be devoid of agonist effects on the endometrium in cell culture studies. Faslodex has been approved for second-line treatment in breast cancer patients and is currently in clinical trials for first-line therapy. Postmenopausal breast cancer patients who have completed antiestrogen therapy but have a recurrence now have another option. Aromatase is an enzyme involved in the production of estrogen. Recently, Femara (Letrozole), an aromatase inhibitor, which was previously approved for treating breast metastasis patients, has won FDA approval for treating postmenopausal women who have taken Nolvadex for five years, after which Nolvadex's efficacy declines. In a clinical study of over 5100 patients randomly assigned to take Femara or a placebo after Nolvadex therapy, it was found that Femara cut the risk of death by 39% for certain breast cancer patients.

1.5 Targeting Enzymatic Cascades

Beyond targeting specific proteins in growth factor signaling cascades, another targeted approach relies on inhibition of enzymatic cascades involved in protein degradation. Velcade (Bortezomib) blocks a key process that regulates protein turnover by inhibiting the activity of the 26S proteasome complex. The proteasome complex rids the cell of short-lived and regulatory proteins important in basic cellular processes such as regulation of cell cycle and modulation of growth factor receptors. Proteins are identified for destruction by an enzymatic cascade that tags the protein with multiple small molecules of ubiquitin. The polyubiquitinated proteins are directed to the 26S proteasome complex where they are shredded by protease activity. Velcade has been approved for the treatment of multiple myeloma and is currently being tested in multiple Phase II clinical trials including NSCLC, colorectal, and non-Hodgkin lymphoma.

2 Therapeutic Agents Used in Targeted Approaches

2.1 Small Molecules

Small molecules (usually possessing molecular weights of less then 500 Da) are attractive therapeutics for a number of reasons: if cell permeability is not limiting, then these molecules have the greatest potential for reaching an intracellular target; greater choices in delivery methods including the ease of oral administration; and offer more options for chemical modification than other approaches like antibody

or gene therapies. The major targets of small molecule inhibitors in current clinical oncology trials affect growth factor receptor signaling pathways. Several examples of small molecule inhibitors that are showing early promise in current clinical trials include: Zarnestra (tipifarnib), a protein farnesylation inhibitor in Phase II for acute myelogenous leukemia; Midostaurin (PKC-412) and MLN-518, Flt-3 inhibitors in Phase II for acute myelogenous leukemia; ZD6474, an inhibitor of the (vascular endothelial growth factor receptor) VEGFR/EGFR family in Phase II for NSCLC and multiple myeloma; BAY43-9006, a raf/PDGFR/VEGFR inhibitor in Phase III for renal cell carcinoma; and CCI-779, an analog of rapamycin and an inhibitor of mTor in Phase III for renal cell carcinoma.

2.2 Antibody-based Therapeutics

Therapeutic antibodies have proven an effective strategy for oncology. Early attempts at antibody therapy were met with limited success. Naked rodent antibodies lacked overall potency and induced a human anti-rodent antibody response preventing the use of repetitive dosing. Further, poor tumor cell penetrance and poor selection of early targets added to lack of efficacious antibody therapeutics. In the early 1980s, human/mouse chimeric antibodies were engineered through recombinant technology and reduced the generation of human anti-therapeutic antibody responses, but did not eliminate them. Advances in molecular immunology have resulted in fully human antibodies as therapeutics that may further reduce antigenicity. Toxicity with this approach is usually attributed to cross reactivity with normal tissue, for example, heart muscle damage associated with the use of Herceptin. Early successes with antibody therapeutics were directed to cell surface antigens in the myeloid lineage that when bound mediated cytolysis by activating complement and antibody-dependent cellular toxicity. Another application of these high specificity and high affinity binding antibodies was to conjugate them to radioisotopes or cytotoxins. Moreover, with the advent of better target selection, antibodies, such as Avastin (bevacizumab) and Erbitux (cetuximab), are having noteworthy effects in solid tumors. There are eight antibody therapeutics that are currently approved by the FDA for the treatment of cancer (Table 1).

Tab. 1 FDA approved antibody-based therapeutics.

Antibody	*Target*	*FDA approval for use [year]*
Rituxan	CD20	Non-Hodgkin's lymphoma (1997)
Herceptin	HER2/EGFR2	Breast cancer (1998)
Mylotarg	CD33/cali-cheamicin	Acute myeloid leukemia (2000)
Campath	CD52	Chronic lymphocytic leukemia (2001)
Zevalin	CD20/90Y	Non-Hodgkin's lymphoma (2002)
Bexxar	CD20	Non-Hodgkin's lymphoma (2003)
Erbitux	EGFR	Colorectal cancer (2004)
Avastin	VEGFR	Colorectal cancer (2004)

2.3 Emerging Therapeutic Agents

Advances in molecular technologies have opened up new areas for unique therapeutic approaches based on functional genomics tools. Therapeutic approaches that are in development stages at various academic and commercial institutions include vaccines, antisense oligonucleotides, and recombinant vaccines. For example, G3139, antisense oligonucleotide against Bcl2, a pro-survival mitochondrial protein, is in preregistration for melanoma. Agents based on functional genomics tools, such as antisense, ribozymes, and RNAi may potentially become stand-alone therapies. They also play an additional role by enabling functional profiling to identify targets and biomarkers. For example, RNAi technology enables any protein target to be inhibited by sequence-specific, double-stranded RNA molecules. siRNA-based approaches are effective and allow for functional characterization of new potential targets in preclinical studies. Other functional genomics tools, such as antisense ribozymes may also prove useful in the clinic as they already have in the research environment.

3 Technological Approaches

3.1 Integrated Clinical Strategies for Diagnosis, Treatment, and Prognosis

Investigation of tumor-specific changes that differentiate cancer cells from other cells in the body is important for identification of novel receptors and pathways, which may be targeted. Greater understanding of cancer biology is also important for discovery and validation of biomarkers. Targeted therapies and predictive biomarkers can potentially guide physicians to eventually treat each patient individually with medication that is personalized and potentially more effective. With the advent of the sequencing of the human genome and high-throughput functional genomics, the identification of possible targets has increased exponentially. Of the 30 000 to 40 000 human genes that have been identified, preliminary analysis indicates that about 60% of these are of known function: 21% are involved in signal transduction, 10% are transcription factors, 5% are protooncogenes and 3% are cell adhesion molecules. This information along with functional analysis of the remaining genes should lead to the identification of new targets in cancer therapeutics.

3.2 High-throughput Genomics Approaches

Expressional analysis is greatly enhanced by the recent advances in high-throughput technologies and in related bioinformatics tools to analyze, interpret, and manage increasing amount of genomic data. Microarray analysis significantly expanded the throughput of genomic studies. For example, hierarchical clustering of expression data revealed distinct groups of epithelial ovarian malignancies. On the basis of microarray data, tumors could be further subdivided into major groupings that correlated both to histological and clinical observations. Microarray-based comparison of gene expression profiles of paired diagnosis-relapse samples from patients with precursor-B acute lymphoblastic leukemia showed that only six genes differed significantly in expression. Microarray technology enables high-throughput

testing of expression and SNP genotyping. Microarrays could be manufactured by direct synthesis of DNA on the chip surface (for example, Affymetrix chips (http://www.affymetrix.com, and NimbleGen (http://www.nimblegen.com/). Microarray could also be produced by spotting materials on the chip surface.

Spotted microarrays may incorporate cDNA, oligonucleotides, and also proteins and functional genomics tools, such as siRNA. Minimum Information about Microarray Experiment (MIAME) is a set of rules aimed at making the microarray results reproducible (http://www.mged.org/Workgroups/MIAME/miame.html.) Microarray data undergoes statistical analysis to identify genes of interest. Statistical microarray analysis (SMA) package is available at http://stat-www.berkeley.edu/users/terry/zarray/Software/smacode.html. SMA is running in an R statistical environment; R (www.r-project.org) is a widely used open-source object-oriented statistical software package. Fixed content arrays (which are mass-produced) can provide many data points; however, sequences of interest may be missing. Microarray experiments could also miss changes in the expression of low-level abundance genes. A significant opportunity exists when combining the throughput of a microarray with the sensitivity of PCR. For example, OpenArray™ Transcript Analysis (BioTrove) uses parallel quantitative PCR to determine transcript copy numbers in samples of interest. OpenArray™ Transcript Analysis platform consumes nanoliter-scale quantities of reagents and samples. Microscope slide-sized OpenArray™ plates contain over 3000 through-holes, which accept 33-nL reactions. By harnessing surface energy, Thru-Hole™ technology creates a precise dispensing action that does not require complex equipment.

3.3 Integrative Approaches

Microarray analyses could be used to identify genes that are induced or suppressed in certain types of tumors and these can be studied as potential targets and biomarkers. Functional characterization of these novel factors is a rate-limiting step. Functional genomics approaches coupled with bioinformatics have the potential to accelerate target and biomarker identification and validation and subsequent development of novel therapeutic approaches and strategies. siRNA technology could be used to selectively probe involvement of genes in the control of proliferation and other cellular processes. Additional studies have demonstrated that siRNA transfection and subsequent processing and analysis could be automated. Automated application of gene specific siRNA produces modified cell populations, which can be examined via batteries of functional tests. Genes with impact on biological processes of interest are selected and investigated as potential targets and biomarkers. Bio-pharmaceutical discovery and development create a demand for conducting a significant number of assays for target validation, lead discovery, and optimization, biomarker support, and other relevant assessments. For example, individual patient's tumor cells may be tested against a panel of siRNA reagents to identify pathways driving tumor growth and progression. This information may lead to formulation of personalized strategies of treatment. To minimize cost, automation becomes very important. Robotics may be used at different stages of the discovery and

development process. A fairly complex experiment could be split into a series of relatively simple steps, similar to Henry Ford's approach to used automobile production. Robots may be positioned to accommodate a very complex experimental workflow, creating an assembly line approach to molecular biology. This experimental approach is termed *Functional Informatics*. (Healthtech Institute Bioinformatics Glossary: http://www.genomicglossaries.com/content/Bioinformatics_gloss.asp).

To make this transformational change happen, several elements are of critical importance: (1) assays have to be reformulated to automation-friendly formats, (2) data acquisition and data analysis have to be automated, and (3) each test system has to be independently validated. Automation drives increases in data volumes, and this in turn necessitates automated data processing and reporting. As data are generated on the same platform, significant efficiency is achieved via consistent data processing, data integration, data storage, and data reporting. As data generation and analysis become integrated on the same platform, an automated analysis via artificial intelligence allows the automated hypothesis generation and testing.

4 Concluding Remarks

Targeted Therapy relies on inhibition of specific signaling pathways and results in significantly fewer adverse effects in clinical settings. Genomic technologies and integrative paradigms such as Functional Informatics have significant potential to accelerate drug discovery and optimize the development of novel targeted therapies.

Keywords

Angiogenesis
The process by which small new blood vessels are formed by budding from existing vessels in both normal and diseased (e.g. tumor) tissue.

Biomimetic Polymer
A polymer whose structure is designed to mimic the properties of a natural macromolecule, for example, a synthetic multivalent ligand designed for receptor interaction.

Controlled Release
Controlled release dosage forms maintain a constant plasma concentration of drug over a prolonged period of time.

Drug Targeting
Guidance of a drug to a diseased cell, or an intracellular compartment within that cell, where it can exert its therapeutic effect. Guidance of drug away from sites of potential toxicity is also a benefit.

Dendrimer
A macromolecule containing symmetrically arranged branches arising from a multifunctional core. Repeated reaction sequences add a precise number of terminal groups at each step or generation.

Endocytosis
Internalization of the cell's plasma membrane to form vesicles that capture macromolecules and particles present in the extracellular fluid and/or bound to membrane-associated receptors. These vesicles then undergo a complex series of fusion events directing the internalized material to an appropriate intracellular compartment.

Endosomotropic
Delivery of molecules to the cell via the endosomal compartment of the cell. Term applied to polymer constructs designed as viral mimetics that can permeabilize the endosomal membrane and thus deliver proteins and oligonucleotides into the cytoplasm of the cell.

Immunoconjugate
An antibody-based conjugate usually containing a covalently bound drug.

Liposome
Lipid-based vesicle used to entrap a drug payload and promote disease-specific targeting.

Lysosomotropic
Delivery of molecules to the cell via the lysosomal compartment of the cell. A term applied to polymer-drug constructs taken into the cell by endocytosis, which contains a linker that is cleaved by lysosomal hydrolases to liberate the drug molecule that diffuses across the lysosomal membrane into the cell.

Micelle
A colloidal aggregate (usually of spherical dimensions) formed in aqueous solution forms molecules that have both hydrophilic (water-loving) and hydrophobic domains (water-hating). They form when the concentration reaches the critical micelle concentration. Both surfactant and block copolymer micelles are being used as drug delivery systems.

Nanomedicines
The umbrella term used to describe nanosized (1–1000 nm) drugs and drug delivery systems used as medicines. This can include molecular medicines (e.g. proteins, antibodies, recombinant fusion proteins and hybrid polymer-protein constructs), but is more generally used to describe multicomponent drug delivery systems such as liposomes (which may also be polymer coated and contain antibody targeting elements), nanoparticles, and polymer therapeutics including polyplexes.

Nanoparticle
Tiny particles, usually of dimension 20 to 500 nm and formed from natural or synthetic polymers that are used to entrap drug for improved drug targeting and controlled release.

Nanomedicine, the Discipline
The newly emerging discipline called *nanomedicine* describes the application of nanotechnology (usually viewed as 1–1000 nm) to the design of systems and devices that can be (1) used to facilitate better understanding of disease pathophysiology and thus enables new target identification for therapeutic intervention; (2) nanoimaging at the cellular and patient level; and (3) design of nanomedicines and nanodiagnostics. Underpinning fields are nanorelated materials, nanorelated engineering and nanorelated toxicology.

Polymer Therapeutics
This is an umbrella term used to describe polymeric drugs, polymer–drug conjugates, polymer–protein conjugates, polymeric micelles to which drug is covalently bound, and multicomponent polyplexes being developed as nonviral vectors. From the industrial standpoint, these nanosized medicines are more like new chemical entities than conventional ''drug delivery systems or formulations'' which simply entrap, solubilize, or control drug release without resorting to chemical conjugation.

Polyplex
The term is usually used to describe the complex formed by a polycation and an anionic oligonucleotide or plasmid. The term interpolyelectrolyte complex (IPEC) is also used.

Effective targeting of drugs (particularly macromolecular therapeutics such as proteins, peptides, and oligonucleotides) to diseased cells, and moreover to the precise intracellular compartment where they are required has proved difficult to achieve. While the last decade has seen a number of drug delivery systems incorporating low molecular weight drugs and proteins enter routine clinical use, inadequate delivery is the single most important factor limiting our ability to utilize molecular medicines to their full potential. The body has evolved a number of very efficient biological barriers to protect itself from the harmful effects of pathogens (bacteria, viruses) and foreign materials such as proteins. These include environmental interfaces such as the gastrointestinal tract and the skin, internal cellular barriers such as the endothelial lining of blood vessels (particularly the tight blood–brain barrier), immune surveillance, and not least the cell membrane and inherent compartmentation of intracellular organelles. The current challenge is to design innovative devices and technologies (including nanomedicines) that will help guide the therapeutic to its correct location of action (drug targeting) and ensure that pharmacological activity is maintained for an adequate duration (controlled release).

1 Introduction

Two distinct approaches are customarily taken in the search for improved medicines. The first area is the identification of a distinctive structure that will make a perfect fit with a unique target in the diseased cell. Theoretically, this should generate the ''perfect'' drug molecule with exquisite therapeutic activity and no side effects. In reality, it is usually difficult to find or synthesize such ''perfect'' drugs. Efforts continue; these include screening of natural product molecules to identify candidates with pharmacological activity, preparation of synthetic low molecular weight drugs via traditional medicinal or combinatorial chemistry, and identification of natural macromolecules, including antibodies, proteins, and oligonucleotides that have inherent biological activity.

The second, and complementary approach is to create a drug delivery system that will act as a vehicle to carry and guide more precisely the above-mentioned agents to their desired site of action. For the last three decades, pharmaceutical scientists, with expertise in cell and molecular biology, chemistry, pharmaceutical technology, and medicine have been working in multidisciplinary teams to better understand the biological rationale for design of effective drug delivery systems. Once gained, this knowledge is used in combination with sophisticated synthetic chemistry, recombinant

molecular biology, and sometimes also materials science and engineering, to construct the delivery system appropriate to the particular drug payload. This article provides an introduction to the field of targeting and intracellular delivery (biological barriers and technologies used for targeting), describes the first-generation technologies carrying low molecular weight drugs and proteins that have already entered routine clinical use over the last decade (i.e. the first ''nanomedicines''), and also reflects upon the challenges that still must be overcome if we are to efficiently deliver macromolecular medicines such as antibodies, proteins, and oligonucleotides into specific intracellular compartments.

The principal challenge remains the identification of safe and effective delivery systems able to localize macromolecular therapeutics to the diseased cells or tissues and once there, to promote their efficient delivery to the required intracellular compartment (*drug targeting*) and ensure that they are made available for the appropriate duration of time (*controlled release*).

1.1 Challenges for Targeting and Intracellular Delivery

Why is this field so important? Advances in the understanding of the molecular basis of diseases has brought expectations that novel medicines, able to dramatically improve treatment of life-threatening, and chronic debilitating diseases, are just around the corner. Despite progress in genomics and proteomics research, it has proved much more difficult – than originally envisaged – to realize effective and practical therapies based on protein-, peptide-, and oligonucleotide-based therapeutics into routine clinical practice. Conversion of such innovative macromolecular therapeutics into medicines has been delayed by the lack of parallel, equivalent investment in enabling ''drug delivery'' technologies. For example, from 1989 to January 2004, there have been more than 900 trials mostly focusing on cancer as a target. There is still no gene therapy medicine approved for routine clinical use. Similarly, while the biotechnology revolution is bringing increasingly widespread use of protein- (particularly antibody) and peptide-based therapeutics, these macromolecular drugs are still administered to the patient parenterally, for example, by injection. There is a pressing need for more convenient to use medicines, perhaps manufactured as a tablet, capsule, transdermal (across the skin) delivery system, or inhalation device, as these formulations are much more convenient for the patient to use at home. Most importantly, there is a pressing need to discover improved therapies (new drugs or drug delivery systems) that can cure life-threatening diseases (e.g. cancer and drug-resistant infectious diseases) and palliate the effects of chronic debilitating diseases (e.g. arthritis, multiple sclerosis, and senile dementia).

1.2 Principles of Drug Targeting and Controlled Release

Since the pioneering work of Paul Ehrlich at the beginning of the last century, the potential benefits of disease-specific targeting, using both chemotherapy and immunotherapy, have been well appreciated. Although progress in recent decades has been remarkable, these concepts have never been fully realized to practice.

Ehrlich coined the phrase ''magic bullet'' to describe targeted therapy. In the modern era, phrases such as ''guided missiles'' or ''stealth delivery systems'' are also often used. Most low molecular weight pharmaceuticals distribute randomly throughout the body after administration and few are perfectly selective in terms of action. Therefore, the desire to identify strategies for better drug targeting has been growing exponentially. Increasingly sophisticated systems are being explored, including engineered devices, technologies of nanoscale size (1–1000 nm) and recombinant or synthetic hybrid molecular conjugates.

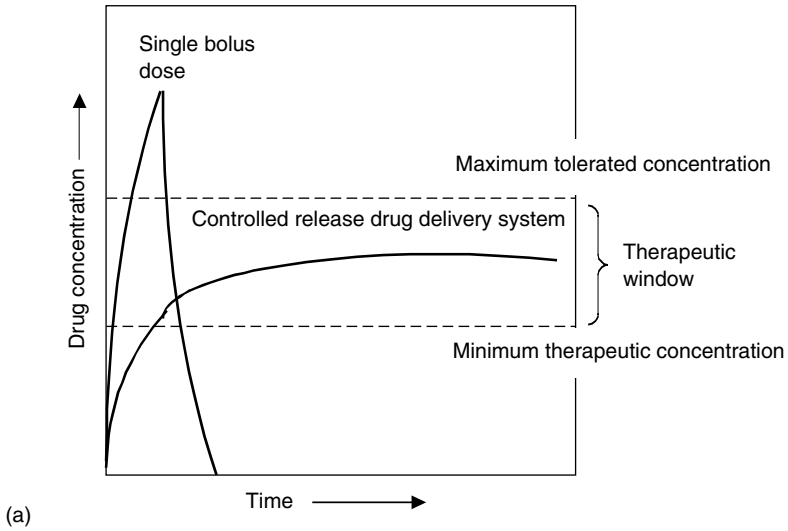
When trying to design an ideal ''drug delivery system,'' it is often necessary to consider two distinct factors. These work in concert to achieve maximum therapeutic benefit. The first is the aforementioned need to deliver the drug to its target site of action that is, *drug targeting*. The second is the need to deliver pharmacologically active drug at an appropriate rate, giving a therapeutic concentration and for an appropriate period of time, the exact duration of which depends on the mechanism of action of the particular compound (Fig. 1a). Minimum toxicity can be achieved by ensuring that drug concentration does not rise above the maximum tolerated concentration. Over the last three decades, many innovative drug delivery systems have been designed to sustain drug levels over a prolonged period; this can be over a day, a month, or even a year. These delivery systems are called *controlled release systems*, and they can have various forms including drug-containing tablets and capsules, polymer-based depots or devices.

Most modern drug delivery systems administered parenterally incorporate both the features of *drug targeting* and *controlled release*. They aim at targeting the drug to the diseased cell, and once there, are programmed to release the drug at an appropriate rate (geared to its mechanism of action) for a suitable duration of time.

It is important to note that drug delivery systems designed for *drug targeting* accomplish this goal at three different levels (Fig. 1b). Many diseases are resident in a single organ; therefore, drug delivery systems can be devised to localize high concentrations of drug locally within that particular organ. This phenomenon has been called *1st order targeting*. Lung targeting is used as an example in Fig. 1b. In this case, the drug may be delivered from the exterior using an inhaler to distribute drug-containing particles onto the lung surface, that is, topically, or alternatively by intravenous administration of a delivery system able to localize to the lung as a result of lung vasculature-specific targeting. While bringing the benefit of elevated local drug concentrations, 1st order targeting has the disadvantage that it is does not focus the agent specifically into diseased cells.

If cell-specific targeting can be achieved, for example, targeting to cancer cells within the lung, the process is referred to as *2nd order targeting*.

The ultimate challenge is often to localize the drug (especially if it is a macromolecular therapeutic) to a specific intracellular compartment within the target cell. This might be an intracellular vacuole if the target is a pathogen (e.g. leishmania, mycobacteria), the cytosol in the case of an antisense oligonucleotide or, for gene therapy, it may be necessary for a plasmid to be delivered to the nucleus. The ability of a drug delivery system to localize to a compartment at the subcellular level has been defined as *3rd order targeting*.



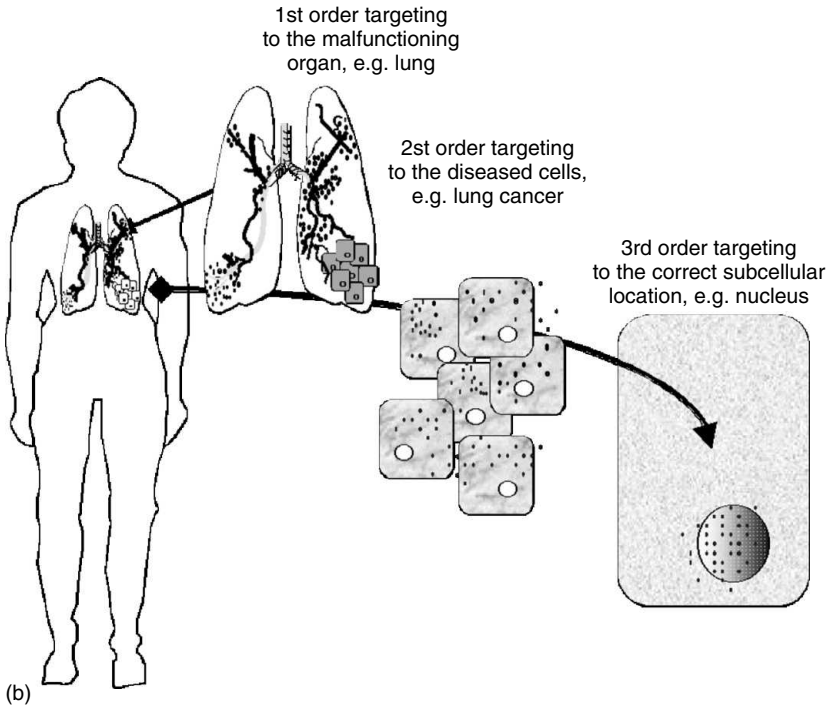


Fig. 1 Rationale for design of targeted drug delivery systems. Panel (a) illustrates the need to release drug at the desired concentration (active but not toxic) over the required period of time. Panel (b) different levels of lung targeting as an illustration of the concepts of first order (to the organ), second order (to the diseased cell within the organ), and third order targeting (to a subcellular compartment within the diseased cell).

1.3 Biological Barriers

1.3.1 Whole Organism Level

Even getting drugs into the body can be a formidable challenge. The body is well protected via the epithelial cell barriers that act as a coat of armor. For example, a layer of columnar epithelial cells lines the gastrointestinal tract, nose, and lung, and the differentiated squamous epithelium that forms skin covers external body surfaces. Depending on their physicochemical nature, low molecular weight drugs will often pass across the gastrointestinal tract, skin, or the pulmonary, nasal, vaginal mucosa. Even so, there are still a number of physicochemical and biological barriers to circumvent to ensure adequate bioavailability. Particular hazards include premature metabolism, for example, by the cytochrome P450 enzymes, and/or ejection of drugs from the very cells they are trying to cross by membrane-localized efflux pumps such as P-glycoprotein. The cytochrome P450 enzyme CYP3A4 is expressed at high levels in the intestinal mucosa and it is known to recognize as substrates more than 50% of drugs administered orally to humans. The complexity of each barrier depends on the particular route of administration and further details can be found in more specialized texts. Table 1 lists the principal routes used for drug (and delivery system) administration. Many specialized *in vitro* models of biological barriers have been established to enable the study of transport processes and to facilitate drug delivery system optimization.

Small, relatively lipophilic molecules have the advantage that they can usually traverse biomembranes. Macromolecular drugs (including proteins, peptides, oligonucleotides) and the newly emerging drug delivery technologies including protein carriers, liposomes, nanoparticles, immunoconjugates, and polymer therapeutics (see below) in general cannot. To gain access to the body, and subsequently travel to those tissues within which the target cells lie, they must either pass across the cells (*transcellular passage*) that comprise the epithelial barrier by hijacking physiological transport processes such as transcytosis or alternatively pass between these cells (*intercellular passage*) as shown schematically in Fig. 2. In the latter case, they must be small enough to pass through the intercellular junction complex or be able to transiently open the tight junctions. Intercellular junctions can be of three types: a tight junction, a gap junction, and a desmosome. Passage of molecules is limited by their size. Whereas the gap junction has a diameter of 2 to 3 nm, the tight junction can be as small as 0.8 to 2.0 nm, so transport across is usually restricted to molecules of $<$200 to 500 Da molecular weight. It should be noted that microparticles and nanoparticles are taken up and transported across the gastrointestinal tract by the immunosurveillance cells called M cells. This physiological pathway has been explored as a route for delivery of vaccines and drugs.

1.3.2 In the Circulation

To bypass these external barriers, many drug delivery systems are injected parenterally (e.g. by intravenous, intraperitoneal, subcutaneous administration etc.). However, irrespective of the route of administration, travel through the bloodstream is usually required to reach the target cells. This presents an additional series of biological hurdles. The reticuloendothelial system (RES), that is, the macrophages in the liver and spleen, is primed to eliminate circulating ''foreign''

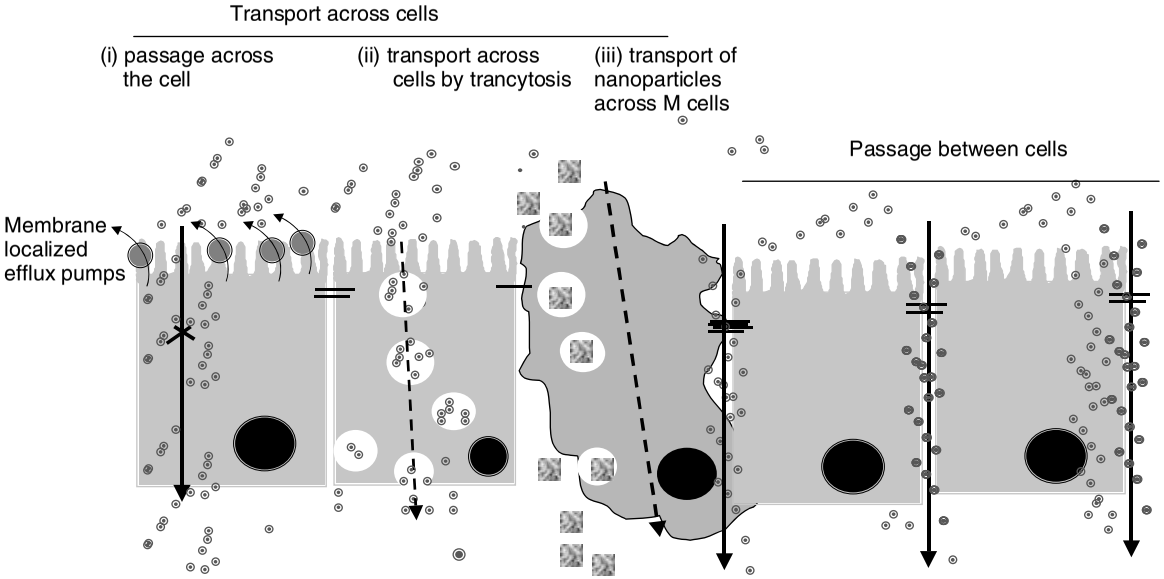

Fig. 2 Possible mechanisms of transport across an epithelial cell barrier. The gastrointestinal tract is given as an example, and in this case, the specialized M cells are also able to take up and transport nanoparticles and microparticles. (i) Transport of low molecular weight compounds (particularly if they are hydrophobic) can occur across the cell by transcellular diffusion or by active transport. (ii and iii) Alternatively, low molecular weight compounds and macromolecules and/or small particles can be transferred by transcytosis. Finally, very small molecules (ions, solutes) can potentially pass through the junctional complex and this movement between cells is termed the *paracellular route*.

Tab. 1 Routes of administration.

Route	*Use*	*Comments*
Noninvasive		
Oral	A wide variety of low molecular weight drugs are administered via this route.	Convenient for the patient. However, poor and irreproducible bioavailability can be a problem. This route is not well suited for delivery of macromolecular drugs that are poorly absorbed and/or degraded in the gastrointestinal tract.
Buccal	An alternative to oral delivery well suited to specific drugs.	Rapid access to brain avoids first pass metabolism in the liver.
Colonic	Can be achieved by use of suppositories or oral formulations designed for time-release or site-specific release in the colon.	Suppositories are a popular alternative to oral delivery in some countries; they can be useful in the event of the patient suffering from nausea or vomiting.
Vaginal	Being used as a means to block HIV virus entry.	Convenient for localized applications such as treatment of sexually transmitted diseases.
Ocular	Topical application to the eye or local injection of drugs expected to act locally.	Eye drops are convenient for the patient to use but often the drug is rapidly removed and it is difficult to maintain therapeutic concentrations.
Pulmonary	Delivery of drugs with target action in the lung or as a means of gaining access to the bloodstream.	The large absorptive surface of the extremely thin lung mucosal membrane and its good blood supply has given hope that this route can be used for systemic delivery of peptides and proteins.

Intranasal	Delivery of drugs that would be inactivated in the GI tract.	Although a convenient route for administration, reproducible delivery can be compromised if the patient has a cold or hay fever.
Topical and transdermal	Topically administered drugs for treatment of skin-related diseases and also the use of transdermal patches to deliver drugs across the skin.	Drugs with suitable correct physicochemical properties pass through the skin into the bloodstream. This has the advantage of avoiding first pass metabolism. Recently, delivery systems that promote transport using iontophoresis, ultrasound, or microneedles have also emerged. These painless techniques transiently disrupt the skin's barrier but permeability can be dependent on age and site of application.
Parenteral		
Local implantation	Use for delivery at the site of disease and to implant controlled release systems.	Ability to place the delivery device at the disease site, for example, brain cancer, blood vessel. Also can be tailored to control release over short or long periods of time. Not suitable for targeted delivery to disseminated disease.
Intravenous, subcutaneous, and intramuscular	Delivery of drugs that would be poorly absorbed using other routes and in circumstances where an immediate effect is required.	The only reliable route of administration for macromolecular drugs and compounds inactivated in the GI tract or poorly absorbed there.
Intraperitoneal	Delivery of drugs expected to act locally, for example, ovarian cancer.	Potential difficulties for repeated administration and rapid transfer to the circulation diminishes regional specific targeting.

particulate matter and ''foreign'' macromolecules, and can accomplish this task within minutes. The tendency of antibodies and blood proteins to adhere to circulating drug delivery systems (opsonization) potentiates RES-mediated clearance. Even if a drug delivery system is designed to target directly accessible cells (e.g. blood cells, the vascular endothelium, or liver cells), efficient targeting can take time and thus can be compromised by rapid RES clearance. The aim is often targeted delivery to cells in the extravascular space. To accomplish this goal, RES-avoiding, long-circulating, delivery systems are used. In this case, the vasculature itself may present a daunting physical barrier due to the simple squamous epithelium (made up of the endothelial cells) that lines the vessels. Depending on overall size and physicochemical properties, exit of the drug delivery system from the bloodstream (extravasation) can be difficult. These features also control subsequent, diffusion-mediated, penetration into a target tissue. The tight endothelial barrier in the brain, the so-called ''blood–brain barrier'' (BBB), is particularly difficult to penetrate.

The blood vessel endothelial cell wall is specifically designed to retain circulating proteins and cells. Smaller macromolecular-based drug carriers, and nanoparticles, usually 5 to 20 nm in size, can escape into extravascular compartments using the routes taken by proteins and antibodies that constantly circulate via more permeable, fenestrated blood vessels, into the lymphatic system and back into the circulation. For instance, they can escape more easily through vessels in the peripheral capillary beds, the peritoneal cavity, liver, and in the alveoli of the lung. In some cases, these smaller carriers also have the ability to utilize transcytosis pathways that facilitate transport of natural macromolecules across the endothelial wall. Once in the interstitial space the extracellular matrix can be an additional barrier. Charged or hydrophobic carriers can bind to it or become entangled there. Moreover, deeper penetration of antibody-targeted systems into a tissue can be compromised by efficient binding to antigen near the blood vessels; the so-called ''antigen-binding barrier''. Premature binding of an antibody to antigen shed into the bloodstream or extracellular fluid also neutralizes targeting potential.

Larger carriers and complexes, such as liposomes and polymer/DNA complexes (polyplexes) usually have a diameter of 30 to 150 nm and consequently they have greater difficulty in escaping normal blood vessels and subsequently penetrating far into complex tissues. Nonetheless, all long-circulating carriers share the ability to selectively extravasate into sites of enhanced vascular permeability, by a process known as *passive targeting* (see below). In disease, enhanced permeability typically arises at sites of local inflammation (e.g. during infection, arthritis) and at sites of new blood vessel formation, for example, the angiogenesis that occurs to sustain tumor development. Even liposomes of diameter up to 800 nm have been found to escape angiogenic vessels.

While small size is advantageous in terms of extravasation and avoidance of the RES surveillance, if the carrier is too small (e.g. a protein of $<60\,000$ Da or a polymer/particle $<40\,000$ Da or $<\sim 5–6$ nm in diameter) there is a high probability of rapid renal elimination via the pores in the kidney glomerulus. This is disadvantageous if a delivery system is removed prematurely before it can access the desired target. However, the

kidney receives ~25% of the cardiac output, so conversely renal filtration has potential for exploitation as a route for drug targeting to renal tubule cells. These cells are physiologically programmed to reabsorb certain small molecules (e.g. folate, saccharides, and amino acids) and some low molecular weight charged or hydrophobic macromolecules. Strategies under investigation have used low molecular weight proteins or synthetic polymers as renal tubule-targeted drug carriers (e.g. lysozyme-naproxen and lysozyme-captopril). The renal tubule cell tropism of antisense oligonucleotides has also been explored as a means to localize their pharmacological activity.

In addition to the above-mentioned physical barriers, in transit, the drug delivery system and its payload encounter a large number of biochemical barriers. Premature metabolism of drug or carrier can occur at every step. Proteases and nucleases are a particular hazard when trying to deliver proteins and oligonucleotides.

1.3.3 Cellular Level

Once a drug delivery system arrives safely at the target cell, yet another series of biological barriers present themselves. These include the physical barrier of the plasma and intracellular vesicle membranes, problems of intracellular organelle compartmentation (e.g. penetration into the nucleus), and a series of biochemical and metabolic barriers; for example, endocytic vesicle pH, the catabolic/metabolic enzymes present lysosomes, cytosol, and other intracellular organelles.

Low molecular weight, lipophilic drugs often readily traverse the membrane by diffusion, facilitated-, or active transport. However, they still have to bypass membrane-localized efflux pumps, which are a particular problem in drug-resistant tumor cells. Generally, natural macromolecules, macromolecular drug delivery systems, liposomes, nanoparticles, and polymer–DNA complexes (polyplexes) cannot easily traverse the plasma membrane. Their cellular uptake is almost exclusively limited to the endocytic route. Figure 3 shows the main intracellular trafficking pathways and illustrates the dynamics of the transport processes, the rapid rates of transfer between compartments, and the local pH encountered. Escaping the endocytic vesicular compartments presents a major challenge for a drug delivery system. This hostile, intravesicle environment can inactivate many low molecular weight drugs, and all proteins, peptides, and oligonucleotides that arrive there unless they rapidly escape into the cytosol or can be protected in transit by the drug delivery vehicle. The membrane-localized ATP driven H^+ pump is responsible for vesicle acidification and pH values of 4.5 to 6.5 are typically seen. This may change in disease. Additionally the lysosomal compartment contains a battery of hydrolytic enzymes (including peptidases and proteases, nucleases, lipases, and glycosidases) well able to degrade all natural macromolecules that arrive there.

As the endocytic pathway is the principal route of entry for targeted delivery systems, its mechanism(s) are of fundamental importance. Endocytosis involves the internalization of plasma membrane in the form of membrane-bounded vesicles. This is a constitutive process in all eukaryotic cell types, although each cell type may have a specialized endocytic machinery to allow it to fulfill particular physiological functions. Endocytosis fulfills a multitude of functions including removal of aging proteins from the extracellular fluids leading to their catabolism;

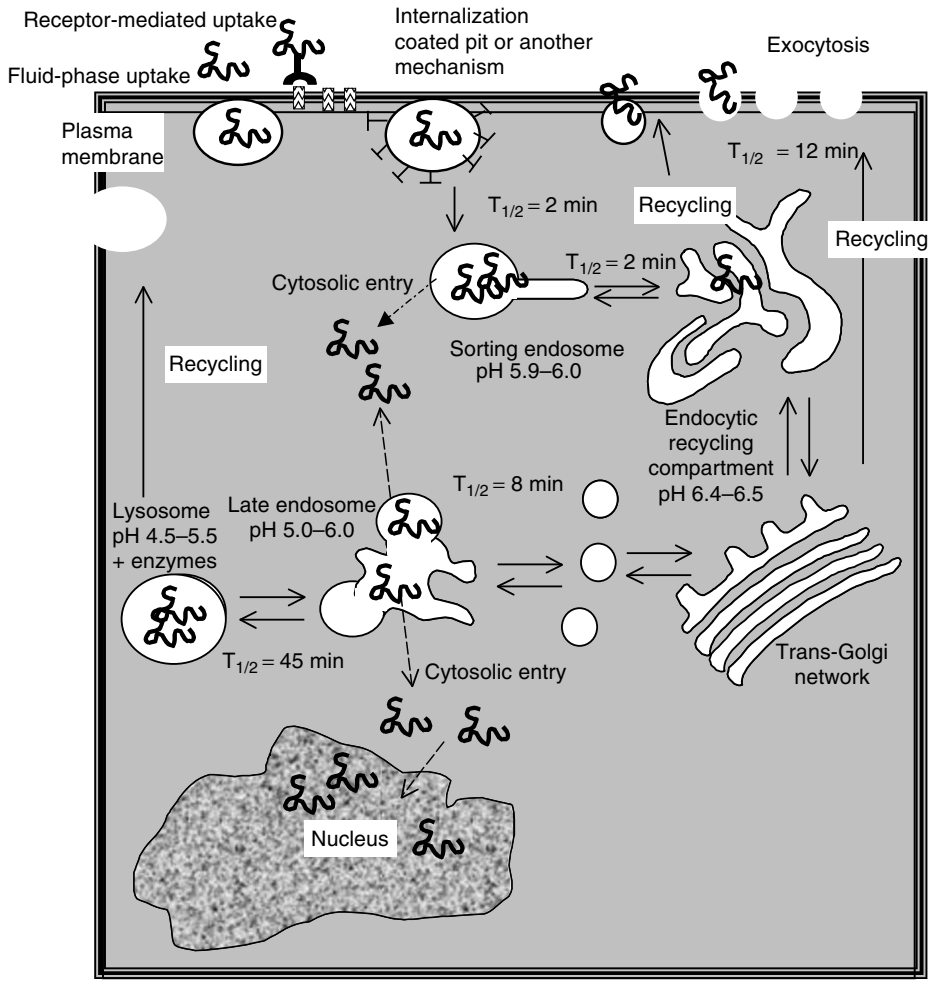

Fig. 3 Schematic diagram showing the main pathways for endocytic uptake and intracellular trafficking of macromolecular and particulate drug carriers. Of particular relevance is the decreasing pH encountered within intracellular vesicles and the potentially rapid exchange between one compartment and another. Uptake can occur simply due to the presence of the delivery system as a solute or colloidal suspension in the extracellular fluid (fluid-phase endocytosis) or as a result of receptor-mediated uptake. The cargo can potentially be directed into endosomal and lysosomal compartments, may be rapidly recycled and eliminated from the cell by exocytosis, or might potentially escape the endosomal vesicular network and localize to other intracellular organelles such as the nucleus.

internalization of nutrients required by the cell for anabolic synthesis (cholesterol, amino acids (via protein degradation), iron etc.), and regulation of plasma membrane receptor number and consequently signaling pathways.

It is noteworthy that there are many potential doorways for entry, and the

mechanisms of vesicle formation are ligand- and cell-type dependent. Internalization can occur via phagocytosis (uptake of larger particles usually by macrophages), clathrin-coated pits (receptor-mediated endocytosis), caveolae (cholesterol enriched domains particularly implicated in endothelial cell transcytosis), and clathrin-independent vesicles (those responsible for micropinocytosis). Uptake of natural molecules is usually triggered by ligand–receptor interaction, and assembly of membrane-associated, multiprotein complexes with signaling cytosolic domains carefully regulating the process of internalization. The membrane composition of vesicles and tubules (lipids and proteins) that comprise the endocytic network is constantly changing. Transfer of the contained cargo is regulated by vesicle–vesicle fusion events controlled by the drop in pH, vesicle membrane curvature, multiprotein complexes on the cytoplasmic face of the vesicle, and also the membrane lipid and protein composition of each compartment. Specific receptors are sorted into pathways that direct them to (1) the lysosomes (e.g. the asialoglycoprotein receptor of liver hepatocytes which traffics to the lysosome); (2) recycle them back to the plasma membrane (e.g. the transferrin/transferrin receptor complex; or (3) the Golgi network (e.g. protein toxins such as ricin).

With the biological rationale for design very much to the fore, current efforts are trying to achieve biomimetic, bioresponsive, macromolecular, and nanosized particulate delivery systems that are able to mimic natural transport vectors such as proteins (including protein toxins) or viruses. The overall goals are (1) design of constructs able to escape the immunosurveillance and metabolic pathways that lead to premature elimination; (2) cell-specific targeting; and (3) cellular entry by translocation across the plasma membrane or, using specific endocytic transport pathways, compartment-specific trafficking.

1.4 Opportunities for Targeting

1.4.1 Passive Targeting to Diseased Tissue

The physicochemical features of many drug delivery systems disadvantage them in terms of targeting disseminated peripheral diseases (e.g. metastatic cancer). However, sometimes these inherent properties can be usefully harnessed in the context of the phenomenon called *passive targeting*. The fact that the RES and/or liver rapidly accumulate >80% of the dose (within 5–10 min) after administration of many nanoparticles, liposomes, and charged (+ve or −ve charge) and/or hydrophobic macromolecular carriers can provide an opportunity for 1st order passive targeting to the liver cells or spleen. In the form of the liposomally entrapped (or lipid-associated) antifungal/ anti-Leishmaniasis drug amphotericin B, cell-specific passive targeting to macrophages harboring pathogens or parasites has been exploited effectively clinically. Another example of passive targeting is the propensity of circulating microparticles (or aggregates formed by interaction of the drug delivery system with plasma proteins or blood cells) of diameter >7 μM to become rapidly trapped in the narrow capillary beds of the lung, again >80% dose within minutes. This also provides an option for 1st order lung-specific passive targeting. However, the approach requires caution due to the risk of pulmonary embolism.

If the carrier can evade RES capture and displays prolonged plasma half-life, it is termed *long circulating*. In this case, it can exhibit *passive targeting* via the "enhanced permeability and retention effect" (EPR effect). First described by Matsumura and Maeda in 1986, EPR-mediated targeting of tumors has been attributed to two principal factors (Fig. 4). First, the disorganized pathology of angiogenic tumor vasculature with its discontinuous endothelium leads to hyperpermeability toward circulating macromolecules and colloidal carriers. Second, the absence of lymphatic drainage in the tumor encourages subsequent tumor retention and progressive accumulation (Fig. 4). The EPR effect is being exploited by a number of drug carriers (including polymer-coated liposomes, polymeric micelles, and polymer–drug conjugates) to promote tumor targeting.

It is now well established that long-circulating macromolecules including albumin, protein-, and polymer–conjugates, polymeric micelles and liposomes accumulate passively in solid tumor tissue by the EPR effect. Intravenously administered polymer–drug conjugates can increase tumor concentration of antitumor drugs up to 70-fold and tumor biopsy following administration of the liposomal anthracyclines Doxil® and DaunoXome™ confirmed EPR-mediated tumor targeting in the clinical setting. The magnitude of targeting achieved by the EPR effect can be surprisingly high, up to ~20% dose/g tumor in murine models, and interestingly the extent of targeting seen (expressed as % dose/g tumor) is often highest in smaller tumors probably because they are more actively involved in angiogenesis. These values are as high as reported for tumor-specific antibodies in rodent tumor models.

1.4.2 Active Targeting to Diseased Cells

Most urgently required are drug delivery systems that do not show inherent liver, spleen, or lung tropism. If the carrier is long circulating, it can be decorated with ligands to promote receptor-mediated uptake, that is, exhibit *active targeting*. Attempts to promote cell-specific delivery have explored a vast array of targeting ligands (see Table 2 for examples), particularly in an endeavor to realize tumor-specific delivery. Most widely explored have been saccharides, peptides, proteins, and antibodies and their fragments. Ideally, the target antigen or receptor must be present at a high density on the cells of interest. It should exhibit homogeneity of expression (preferably with no or minimal expression on normal cells), and the receptor should neither be shed into the bloodstream nor be downregulated upon ligand binding. In addition, receptor fate (whether it is internalized or not) must match the needs of the particular targeted therapeutic being delivered. Some delivery systems are active at the level of the plasma membrane; others have a requirement for internalization. Endogenous ligands present in extracellular fluids (e.g. transferrin or folate) may compete with targeted delivery systems so ideally their concentrations should be low.

The development of monoclonal antibody technology by Kohler and Milstein in the 1970s gave hope that the exquisite specificity of antibody–antigen interaction would provide perfect cell-specific targeting. However, antibody-targeted drug delivery systems have been relatively slow to come into practice. Challenges have included problems in identifying disease-cell specific antigenic determinants; antibody immunogenicity, nonspecific capture of antibodies by cells of the RES due to

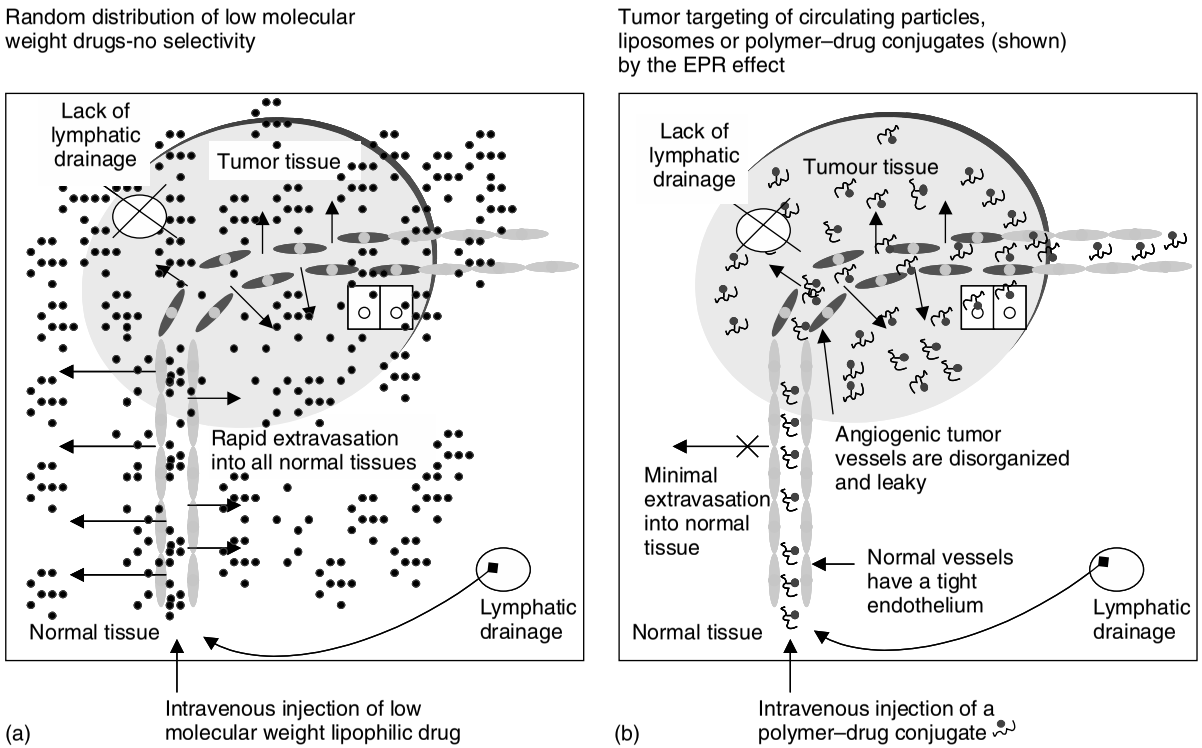

Fig. 4 Tumor targeting by the enhanced permeability and retention (EPR) effect. Panel (a) shows the random distribution of low molecular weight chemotherapy after intravenous injection. Panel (b) shows the vascular retention of a macromolecular drug conjugate (the same would be true for a colloidal carrier) which leads to enhanced extravasation into tumor tissue (via hyperpermeable blood vessels) and the drug delivery system progressively accumulates there due to the absence of lymphatic drainage.

Tab. 2 Ligands used to promote cell-specific targeting.

Ligand	*Target cell*	*Receptor/Antigen*	*Carriers*
Saccharides			
Galactose	Hepatocytes	Asialoglycoprotein receptor	Polymer and protein conjugates
Mannose	Macrophages	Mannose receptor	Polymer and protein conjugates
Sialyl Lewis-X	Endothelial cells	E-selectin	Liposomes, polymers
Peptides and proteins			
MSH	Melanoma	MSH receptor	Polymers
EBV peptide	Lymphocytes	CD21	Polymers
RDG peptides	Endothelial cells	Integrins $\alpha_v\beta_3$	Polymers, peptide-DNA complexes, lipoplexes
Transferrin	Various tumors	Transferrin receptor	Polymers, liposomes
FGF	Various tumors	FGF receptor	Polymers
LDL	Various tumors	LDL receptors	Protein conjugates
Modified albumin			Protein conjugates
Antibodies or fragments			
Anti-Thy 1.2	T lymphocytes	Thy 1.2 antigen	Polymers
Anti-CD19	Multiple myeloma	CD19	Liposomes
Antitransferrin receptor mAb	Various tumors	CD71	Polymers, liposomes, immunoconjugates
B1mAb	Leukemia and lymphoma	BCL1	Polymers
OV-TL	Ovarian carcinoma		Polymers
Anti-ELAM-1, VCAM-1 and ICAM-1 mAbs	Vascular endothelial cells	ELAM-1, VCAM-1 or ICAM-1	Liposomes, immunoconjugates
Anti-HER2-Fab'	Breast cancer	HER2	Liposomes
Anti-VEGF receptor mAb	Vasculature of solid tumors	VEGF receptor	Liposomes
Anti-CD20 mAb	B-cell lymphoma	CD20	Immunoconjugate, liposomes
Anti-TAG72 mAb	Colorectal and other solid tumors	TAG72	Immunoconjugate, liposomes
Anti-EGFR	Glioma	EGFR	Recombinant immunotoxin containing Pseudomonas exotoxin
Other			
Folate	Various tumors, particularly ovarian	Folate receptor	Polymer conjugates and liposomes
Hyaluronic acid	Murine melanoma	CD44	Liposomes

Notes: MSH: melanocyte stimulating hormone; FGF: fibroblast growth factor; EBV peptide: EDPGFFNVE, an Epstein–Barr virus epitope; LDL: low-density lipoprotein.

antibody Fc recognition; generation of antiideotypic antibodies that inactivate the antibody specificity or lead to the formation of immunocomplexes that are rapidly cleared. Immunoconjugates can have large size (Mw (weight average molecular weight) >150 000 Da) and this fact, together with the antigen-binding barrier, can lead to poor tissue penetration. However, exciting progress in the field of therapeutic antibodies (e.g. the breast cancer therapy Herceptin®, the recently approved antiangiogenic antibody Avastin®, and commercialization of the first antibody–drug conjugate Mylotarg®) has revitalized the field of antibody-targeted drug delivery systems. Recombinant techniques are being used to humanize antibodies and the versatility of chemical conjugation is being used to create antibody–(or Fab' fragments) polymer conjugates, and nanoparticle- and liposome-targeted systems.

Other ligands have been widely used to promote active targeting, and a list of examples are given in Table 2. Carbohydrates have been widely explored. For example, mannose can be used to target polymeric and protein drug carriers to macrophages. Galactose promotes targeted delivery to the asialoglycoprotein receptor present on normal hepatocytes and hepatocellular carcinoma. Using polymer–drug conjugates, galactose targeting has been explored clinically with the hope of improving treatment of primary and secondary liver cancer. Liver targeting was verified clinically using clinical gamma camera imaging. It is noteworthy that galactose targeting localizes drug within normal hepatocytes as well as hepatoma, so this approach relies on diffusion of the overall high local drug concentration into neighboring cells to create, what has been termed, a *bystander effect*. Phage display techniques have become popular as a means to identify peptide-mediated disease-specific targeting opportunities. For example, peptide hormones such as melanocyte stimulating hormone (MSH) and somatostatin have been employed as tumor targeting ligands, and RDG-containing peptides have been widely used to localize to β-integrins present on endothelial cells. In this case, RGD-containing cyclic peptides having a disulphide bond between two cysteine residues to constrain structure into a preferable motif have the highest receptor affinity. The fact that some cells, including some tumor cells, have elevated levels of LDL receptors, growth factor receptors (e.g. FGFR and EGFR), and folate receptors has encouraged their exploration as potential targets. For example, folate-targeted liposomes have been used to improve delivery of oligonucleotides and anticancer agents.

1.4.3 How to Realize Intracellular Targeting?

Even on arrival at the target cell, direction of macromolecular medicines and nanosized drug delivery systems to the desired intracellular target remains a significant challenge. If the agent can act at the level of the plasma membrane, the journey is over. If the target lies within the endosome, lysosome, or Golgi, internalization and delivery via the endocytic trafficking pathways is relatively simple. For example, many transferrin-bearing drug delivery systems (including liposomes, nanoparticles, polymer–drug conjugates, and polyplexes) and antitransferrin receptor antibody–drug conjugates have been described. Receptor-mediated internalization leads to rapid and efficient uptake and this has been used, for example, to enhance gene delivery by nonviral vectors. Transfer of internalized macromolecular drugs (e.g.

proteins, oligonucleotides) and drug delivery systems (liposomes, nanoparticles, antibody, and polymer conjugates) to the lysosomal compartment is often unavoidable. Addition of ligands such as galactose, and LDL to various drug delivery systems is used to ensure lysosomotropic delivery. In this context, many polymer-, protein-, or antibody–drug conjugates have been successfully designed to use decreasing pH or lysosomal enzymes as the trigger to liberate low molecular weight conjugates drug. For example, pH-sensitive *cis*-aconityl and hydrazone linkers liberate drugs in acidic environments. In addition, the lysosomal thiol-dependent proteases (such as cathepsin B) have been widely used to activate polymer–drug conjugates synthesized to contain peptidyl polymer-drug linkers that are enzyme substrates, or designed using a polymeric carrier (e.g. polyglutamic acid) whose backbone is degraded by these enzymes.

The main challenges that remain are targeted delivery to other intracellular compartments and transfer of macromolecular medicines into the cytosol and/or the nucleus, and the barriers to gene delivery have been well documented. Several strategies are being explored to facilitate cytosolic delivery (Fig. 5). These include (1) improved transfer across the plasma membrane using fusogenic liposomes, membrane translocating peptides, pore-forming proteins, and membrane-active peptides; (2) following endocytic uptake, transfer out of the endosomal compartment into the cytosol with the aid of pH-sensitive endosomolytic polymers or peptides, pH-sensitive fusogenic liposomes and recombinant proteins; and (3) tailoring bioresponsive linkers (usually pH-sensitive or protease sensitive) to liberate a drug payload from polymeric and protein carriers when exposed to the appropriate trigger in the endosomal pathway.

Membrane translocation is a key step. It is becoming increasingly evident that many proteins and receptors can bypass the classical endocytic pathways to enter the cell, as they are equipped with signal peptide motifs that promote translocation across the plasma membrane (Table 3). Similarly, viruses and toxins have peptide sequences that change conformation on entry into the acidic endosome and permeabilize the endosomal membrane facilitating entry. As these peptide motifs become characterized, they are increasingly incorporated into drug delivery systems to facilitate cytosolic access, either using hybrid, recombinant proteins or with the aid of synthetic chemistry to incorporate them into a polymeric, liposomal, or nanoparticulate carriers.

As well as the peptidyl membrane translocating sequences, peptides that are membrane active at pH 7.4, such as the bee venom toxin melittin, are also being explored as components of drug targeting systems. However, in most cases, the pH gradient between extracellular fluid and the endosomal/lysosomal compartments is the important biotrigger used to promote delivery. As an alternative to peptides, a growing number of pH-responsive endosomolytic polymers have been synthesized as vectors for plasmid and protein delivery. Potentially, their reduced or lack of immunogenicity provides greater suitability for *in vivo* administration. Polymers used include polycations such as polyethyleneimine and polylysine, polyanions such as polypropylacrylic acid derivatives, amphoteric polymers such as linear polyamidoamines, and the hyperbranched polyamidoamine dendrimers. Their exact mechanism of endosomal permeabilization is the subject of some

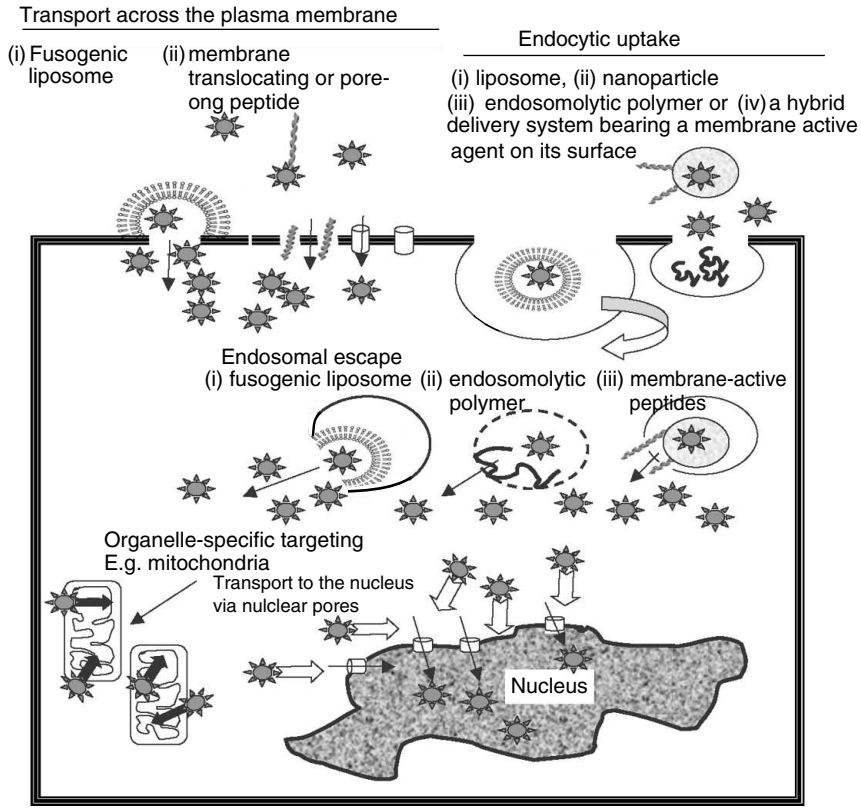

Fig. 5 Vectors used to promote cytosolic access and intracellular targeting. Three main approaches are used; vectors designed to fuse with the plasma membrane; vectors that can pass across the plasma membrane passage, and vectors that promote cytosolic access and/or organelle-specific targeting following endocytic uptake and entry into the endosomal compartments.

debate. It has been suggested that protonation of polycations results in swelling, and this, together with the influx of Cl^- ions and consequent osmotic effects, cause membrane destabilization. This is called the *proton sponge hypothesis*. However, it is clear that not all polycations act in this way. Linear polyamidoamines and polyamidoamine dendrimers seem to interact directly with the membrane to cause perturbation and perhaps pore formation. In the context of liposomal delivery, cationic helper lipids, for example, dioleoylphosphatidylethanolamine (DOPE), have been used to promote fusion in acidic pH environments.

Efficient delivery into the cytosol can be sufficient to ensure pharmacological activity of many macromolecular medicines, for example, antisense oligonucleotides and protein toxins. However, many oligonucleotides, plasmids, and protein drugs must subsequently traffic to the nucleus to achieve the desired effect. Stability of vector (and payload) in the cytosol and an appropriate rate of dissociation to deliver the payload can be problematic. Movement in the cytosol by diffusion can

Tab. 3 Motifs used to promote intracellular delivery targeting.

Ligand	*Function*	*Carrier/Use*
Membrane translocating peptides		
TAT protein transduction domain of HIV	Enhances endosomal escape after endocytic uptake	Fusion proteins or polymer conjugates
Herpes simplex virus type-1 22 protein – VP22	Facilitates an export-neighboring cell protein uptake pathway	Fusion proteins, plasmid delivery
Hydrophobic membrane permeable sequences (MPS) for example, AAVALLPAVLLALLAP	Delivers proteins and peptides across the plasma membrane Enhances endosomal escape after endocytic uptake	Recombinant fusion proteins or chemically synthesized peptide conjugates
Rhinovirus N-terminal peptide VP-1	pH-dependent, enhances endosomal escape after endocytic uptake	Polymers and polyplexes
Influenza virus N-terminal peptide HA-2	pH-dependent, enhances endosomal escape after endocytic uptake	Polymers and polyplexes
GALA	pH-dependent, enhances endosomal escape after endocytic uptake	Polymers and polyplexes
Membrane-active peptides		
Melittin	Pore-forming peptide from bee venom	Polymers and polyplexes
KALA		Polymers and polyplexes
Gramicidin S	Cationic peptide	Liposomes
Polyarginine ($n = 6 - 8$)	Cationic peptide	Polymers
Compartment-specific targeting motifs		
Lipophilic triphenylphosphonium cation	Localizes to mitochondria	Targeting drugs for example, antioxidants to mitochondria
KDEL motif	Promotes endoplasmic reticulum localization	Targeting oligonucleotides, antibodies, and toxins
A cluster of basic amino acids for example, PKKKRKV	Nuclear localization signals that promote nuclear pore binding before transfer to nucleus	Polyplexes designed for gene delivery, fusion proteins

be haphazard and slow, although it has been suggested that some polyplexes are more rapidly translocated to the perinuclear region of the cell in association with microtubules. Incorporation of peptidyl nuclear localization sequences (NLS) that have clusters of four or more cationic amino acids have become popular to promote nuclear trafficking and entry. Even so, nuclear entry of larger macromolecular and particulate carriers can be difficult if the cells are not dividing. Physiologically, macromolecules are imported through the nuclear pores, and there are approximately 3000 to 4000 pores per nucleus. However, in the closed state they will only allow passage of molecules <9 nm in diameter and even when open their diameter is only 26 nm.

With the realization that many diseases can be pinpointed to dysfunction of a specific intracellular compartment (or protein localized therein), many are now trying to design drug targeting systems aimed at specific intracellular organelles. For example, mitochondria dysfunction contributes to a wide number of diseases including, obesity, neurodegenerative diseases, ischemia-reperfusion injury, and cancer. Additionally, there are some 40 different lysosomal storage diseases that have a genetic basis, and it is known that lysosomal/endosomal malfunction can lead to accumulation of products such as lipofuscin, which is implicated in the progression of age-related neurodegeneration, for example, in Alzheimer's disease. A number of strategies are being explored as a means of targeting mitochondria. Interesting concepts at the early stage of development include ''mitochondriotropic'' vesicles prepared from dequalinium (diameter 70–700 nm) and use of mitochondrial signal peptides (MLS-peptide), both of which seem to promote mitochondrial targeting. Peptide localization signals are also being explored as tools for reaching other intracellular compartments, for example, to carry peptides and fluorophores to peroxisomes and for noninvasive cytosolic delivery of peptides and proteins.

1.5 Devices, Technologies, and Nanomedicines

Given the complex journey required to circumvent all these biological barriers, the ideal targeted delivery system will inevitably be multicomponent. It must be able to gain access to the body, and subsequently move through the body without recognition as ''foreign'' by the immunosurveillance systems. It must be biomimetic in the sense that it will be able to utilize natural transport pathways (such as transcytosis, endocytosis) and natural receptor-mediated targeting strategies at both the cellular and subcellular level to achieve the end goal. Ever more sophisticated devices are increasingly used to gain access to the body. These devices can be as simple as the syringe, or as complex as pulmonary inhalers and transdermal devices (including microneedle injectors, and the gene gun which is used to transiently physically damage the skin and thus allow particulate access). Sophisticated multicomponent oral delivery systems have also been designed for local and/or timed release. A detailed description of these devices is beyond the scope of this article.

While natural and synthetic polymers have traditionally found use as pharmaceutical excipients and biomedical polymers, it is important to note their expanding role as components of a wide variety of drug delivery systems. They are utilized to fabricate

devices, rate-controlling coatings, hydrogels for topical and parenteral controlled release, and as biodegradable polymeric implanted matrices for local controlled release of drugs, peptides, and proteins. Not least, the field of polymer therapeutics is now becoming well established and polymers are often components of other types of delivery vectors (see below).

At one time, antibody conjugates, liposomes, nanoparticles, and polymer conjugates were viewed as competing approaches. Naively it was thought that one technology would emerge as a universal platform for all targeting applications. It soon became evident that each has its individual advantages and disadvantages. Antibodies have potential for selective targeting, but even as humanized proteins they can be immunogenic, their pharmacokinetics is governed by molecular weight, and they have a limited drug carrying capacity. Liposomes have a high drug carrying capacity, but stability can be an issue (either releasing drug too quickly or entrapping drug too strongly) and they are prone to RES capture. Similarly, it has proven difficult to steer nanoparticles away from the RES and they can have relatively lower (than liposomes) drug carrying capacity. The versatility of synthetic polymer chemistry provides a unique opportunity to tailor synthetic, biomimetic, molecules having specific molecular weight and particular architecture. For linear polymers, this can provide multivalency needed for receptor recognition, and using dendrimer chemistry controlled 3D architecture can be achieved. In all cases, the polymer-drug linker can be tailored to facilitate site-specific drug release. However, the drug carrying capacity of polymer–drug conjugates is relatively low, conjugate structure can be complex and heterogeneous presenting challenges for characterization. Particular care must be taken to ensure that potential toxicity and/or immunogenicity of parenterally administered synthetic macromolecules is carefully addressed, particularly if the polymer is not biodegradable. There has been growing concern that polymeric nanoparticles, which have a particularly high surface area to volume ratio, could be exceptionally dangerous. However, even in this case any toxicity observed will clearly depend on route of administration, frequency of administration and the polymer (and chemistry) used to prepare the nanoparticle.

With the realization that an ideal platform for drug delivery would marry the benefits of these approaches, over the last decade families of hybrid, nanosized technologies have emerged. In general, they have multiple components optimized for each specific application considering location of the target site and nature of the drug payload to be delivered. There has been exponential growth in the transfer of such technologies into clinical development, and the number of Regulatory Authority approved products is growing year on year (see below). These factors underline the importance of these technologies as the first generation of ''nanomedicines'' (Fig. 6).

2 Vectors: Design, Applications, and Clinical Status

The literature relating to potential drug targeting systems increases year on year. Many claim design and/or synthesis of new drug delivery technologies. Where supporting biological data are provided, the vast majority of experiments are conducted *in vitro*. While these studies provide

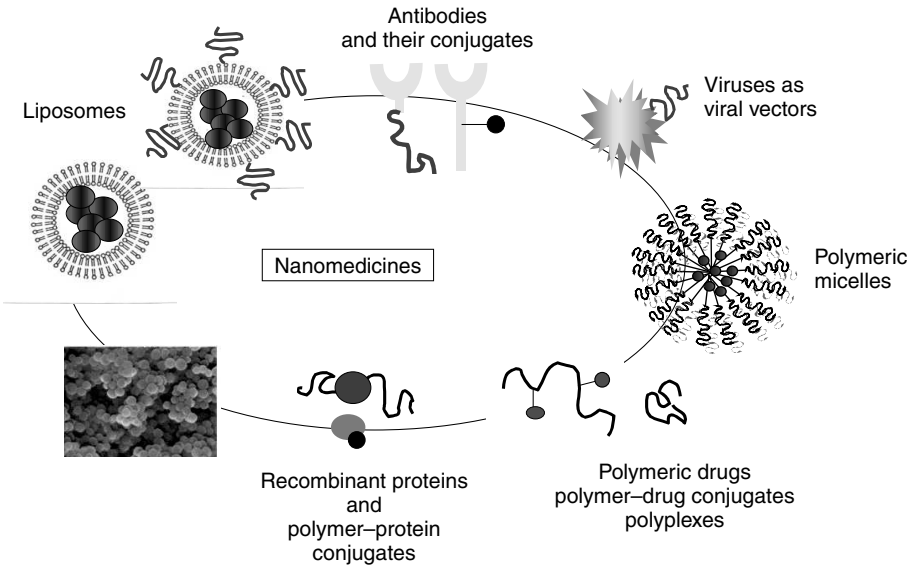

Fig. 6 Vectors that can be described as the first "nanomedicines."

the opportunity to quantitate receptor-mediated uptake by the target cells, we get an early impression of pharmacological potential, and it helps define intracellular localization; experience has shown that such *in vitro* assays rarely have value in predicting *in vivo* targeting potential. Nearly all technologies tested *in vivo* fail due to (1) inability to reach the target cell (often due to RES clearance); (2) inability to reach the correct intracellular compartment on arrival at the target cell; (3) inability to release/deliver drug at the appropriate rate on arrival at the target cell; and (4) not least the fact that many vectors display unacceptable toxicity and/or immunogenicity prohibiting safe human use.

In this section, only those vectors having well established *in vivo* and clinical targeting ability are described. In most cases, new technologies have been first explored in the context of cancer therapy. Globally over 6 million people die of cancers each year. Cure is only possible in ~35% of cases diagnosed, and commonly used cytotoxic chemotherapy is relatively ineffective due to lack of drug selectivity, nonspecific damage to healthy tissue, and multiple mechanisms of drug resistance (<5% of cures). The pressing medical need makes it ethically justifiable to administer novel drug delivery systems to cancer patients where the potential benefits far outweigh any risks associated with these new technologies. Once therapeutic benefit, and clinical safety of other vectors is established in cancer patients, exploitation in therapeutic indications has followed.

2.1 Liposomes

Liposomes were discovered in 1965 by Bangham and at that time used as model membranes. Since the pioneering work of Gregoriadis and Ryman in the 1970s,

liposomes have become widely used for targeted delivery of drugs, proteins, vaccines, and oligonucleotides. Several liposomal products have been approved as novel anticancer therapies, and for delivery of amphotericin B to treat opportunistic infections (Table 4). These vesicular carriers are prepared from phospholipids and cholesterol to form lipid bilayer-bounded vesicles. A single bilayer (unilamellar) or multiple bilayers (multilamellar) are used to entrap an aqueous interior (Fig. 7). Typically, those liposomes used clinically have a diameter of 80 to 150 nm. Hydrophilic drugs, including proteins, are entrapped in the aqueous interior and hydrophobic drugs carried within the lipid bilayer. Amphiphilic drugs that are weak bases or weak acids can be loaded into the liposomal interior using remote loading methods such as ammonium sulfate for doxorubicin and a pH-gradient method for vincristine to give high intravesicle concentrations. Alteration of their lipid composition (sometimes using cationic or anionic lipids) and/or the cholesterol:lipid ratio has been used to modulate properties. For example, cationic liposomes have been used to complex DNA and oligonucleotides on their surface.

The first liposomal formulations had major disadvantages including poor plasma stability, rapid blood clearance by the RES, and difficulty of manufacture on a commercial scale. However, these issues have been largely overcome using second-generation liposomes containing cholesterol to improve stability and also a hydrophilic polymer coating (particularly using polyethyleneglycol (PEG), so-called PEGylation) to minimize RES uptake and thus prolong plasma circulation. The PEGylated or ''Stealth'' liposomes are also able to capitalize on the EPR effect to promote passive tumor targeting. Although liposomes can be internalized by endocytosis, it is thought that delivery of entrapped antitumor agents is largely due to diffusion of drug out of the liposomes and into tumor cells. To promote receptor-mediated targeting of liposomes (active targeting) and cellular internalization, the field of ligand-targeted liposomes (LTLs) has been growing. For example, liposomes have been prepared with antibodies (or their fragments) on their surface. For example, anti-HER2 to target HER2-overexpressing breast cancer; anti-β–integrin Fab to target nonsmall cell lung cancer; antihuman E-selectin to localize to activated endothelial cells; folate and

Tab. 4 Examples of liposomal formulations in clinical use and clinical development.

Product	*Status*	*Payload*	*Indication*
DaunoXome®	Market	Daunorubicin	Cancer
Doxil®/Caelyx®	Market	Doxorubicin	Cancer
Myocet®	Market	Doxorubicin	Cancer
Ambisome®	Market	Amphotericin B	Fungal infections
Amphotech®	Market	Amphotericin B	Fungal infections
Liposomal-MTO	Phase I	Mitoxantrone (MTO)	Cancer
Aroplatin	Phase I/II	Platinate	Cancer
ATRA-IV	Phase I/II	Retinoic acid	Cancer
NX211	Phase I/II	A camptothecin	Cancer

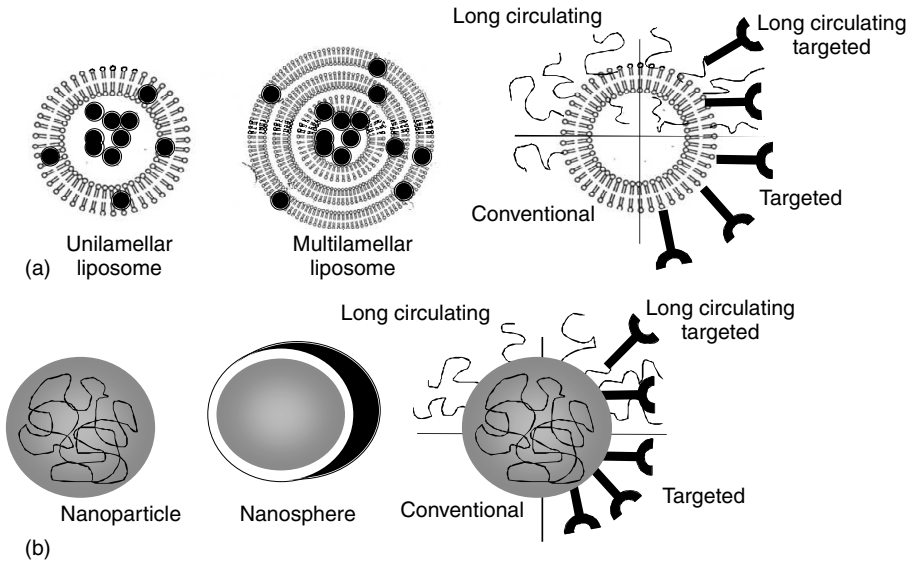

Fig. 7 Colloidal carriers used for drug targeting. A variety of liposomal (panel a) and nanoparticle (panel b) drug delivery systems have been developed for targeted drug delivery. The liposomal carriers can be unilamellar or multilamellar, drug can be entrapped in the aqueous core or within the lipid bilayer depending on its physicochemical nature. Nanoparticles can be made as a polymer matrix with drug entrapped in the polymer matrix, or as a nanosphere entrapping drug in the core. In both cases, ligands can be added to the surface to promote receptor-mediated targeting and a polymer coating applied to the surface to prolong plasma circulation times (usually PEGylation).

hyaluronic acid to target melanoma. PEG-coated liposomes containing cationic lipid have been shown to target chondroitin sulfate proteoglycans overexpressed on the surface of highly metastatic tumor cells. In addition, other experiments have reported neovascular targeting properties of cationic liposomes labeled with the fluorescent dye rhodamine in samples derived from patients with transitional cell cancer of the urinary bladder.

Clinical success of the anthracycline-containing liposomal formulations DaunoXome®, Myocet®, and Doxil® (called Caelyx® in Europe), both as single agents, and more recently as components of combination chemotherapy, really established liposomes as important drug carriers. The DaunoXome® aqueous formulation is composed of distearoylphosphatidylcholine (DSPC), cholesterol, and daunorubicin in a weight ratio of 18 : 7 : 1; that is, it has a daunorubicin concentration of 2 mg mL^{-1}. The liposomes are unilamellar vesicles of diameter ~45 nm. In contrast, Doxil® was the first polymer-coated liposome to come on the market. In this case, the vesicles are composed of hydrogenated soy phosphatidylcholine (HSPC); cholesterol; and diphosphatidylethanolamine (DSPE) conjugated to PEG in the ratio 56 : 38 : 5. The formulation consists of unilamellar vesicles of diameter ~80 to 90 nm and they contain doxorubicin (2 mg mL^{-1}). Doxil® was first approved as a treatment for AIDS-related Kaposi's sarcoma in patients with disease resistant to other chemotherapy or

in patients who are intolerant to such therapy, but now it is also used as a treatment for metastatic ovarian carcinoma (when disease is refractory to both paclitaxel- and platinum-based chemotherapy regimens) and breast cancer. Proof of concept that liposomes could increase anticancer agent activity and reduce toxicity has led to their further development as carriers of other anticancer agents including platinates, camptothecins, mitoxantrone, and vincristine.

Use of liposomal formulations is not limited to tumor targeting. Other uses include delivery of amphotericin B (AmBisome®) to treat various fungal infections and visceral leishmaniasis, antibiotics (Mikasome®), and for targeting radiotherapy. They are also currently under intensive development as vectors for vaccine delivery, antisense delivery, and for use as gene delivery vectors.

2.2 Antibodies, Proteins, and Fusion Proteins

Antibodies and proteins have long been considered as therapeutic agents in their own right and as components of targetable drug carriers. It is only through the last decade, however, that they have really begun to realize this potential. In the context of drug targeting, conjugates can be prepared either by chemical conjugation of drug or, in the case of protein therapeutics, often the conjugate is prepared by recombinant technology. Not only are antibodies themselves used as vehicles for targeted delivery, as mentioned above, they (or antibody fragments) are often used as the site-directing components of other delivery systems including liposomes, polymer conjugates, and nanoparticles.

Early murine antibodies were beset with problems of poor specificity and immunogenicity. However, the ability to humanize, and most recently prepare chimeric antibodies is rapidly generating a successful pipeline of novel targeted pharmaceuticals (Table 5). Seventeen therapeutic antibodies have entered the market, and there is an enormous pipeline of antibody-based products (>350) coming through clinical development.

Therapeutic antibodies can be divided into several categories according to their mechanism of action.

1. They can block the action of another molecule (i.e. act as an antagonist) and examples in this class include antibodies that bind to soluble ligands such as antivascular endothelial growth factor (VEGF), and antitumor necrosis factor (TNF) antibodies.
2. They can stimulate a biological response (i.e. act as an agonist).
3. They kill target cells through immune-mediated mechanisms, for example, the antitumor antibodies Rituxan® and Herceptin®.
4. They can be used to direct radiotherapy, toxins or other drug carrier systems (liposomes, nanoparticles, and polymer conjugates) to a target tissue.

Ideally, target antigens will have 1000-fold greater expression on the target cell than seen on normal tissues and the monoclonal antibody derived against the target should have high affinity. Often in the complex *in vivo* environment, this degree of selectivity has been difficult to achieve. With the aim of minimizing the biological barriers to be encountered, the most successful early products were designed to localize to cells circulating in the bloodstream. For example, the anti-CD20 antibody Rituxan® developed as a treatment for relapsed or refractory non-Hodgkin's lymphoma (NHL). Similarly,

Tab. 5 Monoclonal antibody-based products.

Antibody	***Target***	***Payload***	***Use***
Therapeutic antibodies			
Rituxan®:	CD20	Inherent activity	CD20 +ve non-Hodgkin's lymphoma – mediates antibody-dependent cytolysis
Herceptin®	HER2	Inherent activity	HER2 +ve breast cancer – mediates antibody-dependent cytolysis
Antibody-drug conjugates			
Mylotarg®	CD33	Calicheamicin	Acute myeloid leukemia – taken into the cell by endocytosis
Radioimmunotherapeutics			
Tositumomab®	CD20	[^{131}I]iodide	Non-Hodgkin's lymphoma-targeted radiotherapy
Zevalin®	CD20	^{90}Yttrium	Non-Hodgkin's lymphoma-targeted radiotherapy
Immunotoxins			
Anti-B4-blocked ricin	CD19	Blocked ricin	Targeted immunotoxin non-Hodgkin's lymphoma
Anti-Tac(Fv)-PE38 (LMB2)	CD25	*Pseudomonas* exotoxin fusion protein	Hematological malignancies

the first immunoconjugate to enter routine clinical use was an anti-CD33 antibody conjugated to the natural product anticancer agent calicheamicin (Mylotarg®). In this case, it is used as a treatment for acute myeloid leukemia (AML). Antibodies have not only been used to carry chemotherapy, but they also offer a unique opportunity to target radiotherapy and highly potent protein toxins (e.g. ricin, diphtheria toxin, and pseudomonas exotoxin) to tumor cells. Two radioimmunoconjugates have been approved for clinical use (Zevalin® and Bexxar®) and both utilize an anti-CD20 antibody linked to a chelating agent carrying a radionuclide as treatments for refractory NHL patients.

This year the recombinant humanized monoclonal antibody Avastin™ was approved as the first anticancer agent that works by preventing the formation of new blood vessels (angiogenesis). Avastin™ acts by binding vascular endothelial growth factor (VEGF) preventing its interaction with VEGF receptors (Flt-1 and KDR) on the surface of endothelial cells. The endothelial cell is also a relatively easily accessible target to circulating antibody. In this case, the mechanism of action is inhibition of new blood vessel formation (angiogenesis) and when administered intravenously together with a combination of anticancer drugs (including ironotecan, 5-fluorouracil (5FU), and leucovorin), Avastin™ extends colon cancer patient survival time.

In the future it will be essential to identify a library of antibodies (acting by themselves as therapeutics in their own right or as components of drug delivery systems) that will effectively target those common solid tumors that are the major cause of mortality (e.g. breast, prostate, lung, and gastrointestinal cancers). These tumors are inherently more difficult to

access using macromolecular and vesicular/particulate drug carriers due to relatively poor tumor vascularization and the difficulty of deep penetration into the tumor tissue following extravasation. The recent commercialization of Herceptin®, a new treatment for breast cancer, has been an important step forward. This monoclonal antibody recognizes the HER2 receptor on breast cancer cells and acts by slowing or stopping cell growth. It is only effective in treating those 15 to 25% of breast cancer patients who are receptor +ve and is given to patients in combination with chemotherapy to treat advanced metastatic disease.

Use of proteins (other than antibodies) and peptides to promote targeted drug delivery has also been widely explored, but mostly in preclinical studies. Early studies focused on natural carrier proteins such as albumin, modified albumin, and low-density lipoprotein (LDL). Many peptides have been explored as potential tumor targeting ligands. In this case, an ^{111}indium-labeled analog of the peptide somatostin (Octreoscan®) is used as a diagnostic imaging agent. The ligand localizes to primary and metastatic neuroendocrine tumors bearing somatostatin receptors, and clinical studies are also ongoing to see whether similar analogs can also target therapeutic levels of radioactivity.

2.3 Nanoparticles

Although nanotechnology is becoming very fashionable, Speiser and colleagues had already described the first nanoparticles for drug delivery in the 1970s. Since then there have been numerous studies examining their potential as targetable drug carriers in the context of parenteral administration, in particular for targeting anticancer agents, for oral administration, and most recently for promoting transport across the blood–brain barrier. Nanoparticles have been defined as colloidal carriers of diameter 1 to 1000 nm. They are usually made from natural or synthetic polymers, but recent technology has been exploring the possibility of making nanoparticles from the active drug substance itself. The polymers used can be preformed, for example, poly(lactic acid), and manufacture achieved by emulsion evaporation, precipitation, or salting out procedures. Alternatively, they are prepared by polymerization of monomers, for example, poly(alkylcyanoacrylate) nanoparticles. In some cases, for example, albumin nanoparticles, manufacture is achieved by addition of crosslinking agents. Structures are prepared as nanoparticles composed of a polymer matrix, or nanocapsules with a polymer shell surrounding an open or filled core (Fig. 7). The latter can be achieved by interfacial polymerization. Nanoparticles administered intravenously are particularly prone to opsonization and rapid elimination by RES clearance, so surface modification by addition of polymers (e.g. poloxamers and PEG) has become popular as an attempt to overcome this problem.

The technology is so versatile that nanoparticles can be prepared to contain low molecular weight chemotherapy, peptides, and proteins, and oligonucleotides. However, despite the vast number of preclinical studies, so far it has proved relatively difficult to transfer nanoparticulate drug carriers into clinical practice. Certain types of nanoparticles have shown the ability to reverse multidrug resistance (MDR), which is a major problem in cancer chemotherapy. Nanoparticles are being explored for the selective delivery of oligonucleotides to tumor cells.

An early problem was identification of long-circulating nanoparticles made from biodegradable, biocompatible polymers that would be safely eliminated after achieving the targeting objective. Although progress has been made, the most advanced systems at present are the albumin nanoparticles used as diagnostics and targetable carriers for the anticancer agent paclitaxel. In fact, albumin nanoparticles containing paclitaxel (Abraxane™) that have recently been undergoing extensive clinical studies in breast cancer patients with metastatic disease have shown promising early results. A nanoparticle-based MRI contrast agent, Endorem®, is already on the market, and this superparamagnetic, ferumoxide nanoparticle stabilized on the surface using dextran is used to diagnose liver lesions, particularly cancer metastases in the liver.

2.4 Polymer conjugates

The term *polymer therapeutics* has been used as an umbrella term to describe rationally designed polymeric drugs, polymer–drug and polymer–protein conjugates, polymeric micelles containing covalently bound drug and polyplexes for nucleic acid delivery (Fig. 8). Successful clinical application of polymer–protein conjugates (Table 6) and promising clinical

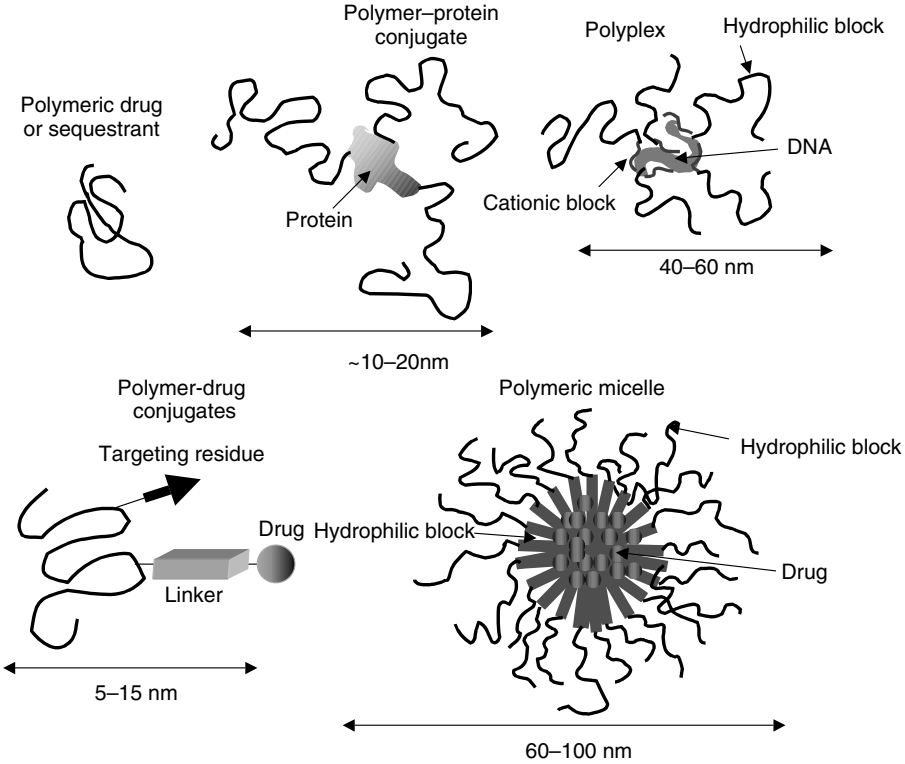

Fig. 8 A schematic diagram showing the range of polymer-based drugs and delivery systems that fall under the umbrella term *polymer therapeutics*.

Tab. 6 Polymer therapeutics in the market or transferred into clinical development.

Compound	*Name*	*Status*	*Indication*
Polymeric drugs			
Poly(alanine, lysine, glutamic acid, tyrosine)	Copaxone®	Market	Multiple sclerosis
Poly(allylamine)	Renagel®	Market	End-stage renal failure
Dextrin-2-sulfate	Emmelle® gel	Market	HIV/AIDS – a vaginal virucide formulated as a gel
Dextrin-2-sulfate		Phase III	HIV/AIDS – polymer administered intraperitoneally
Poly(I):Poly(C)	Ampligen®	Phase III	Chronic fatigue immune dysfunction (myalgic encephalomyelitis; ME)
Polyvalent, polylysine dendrimer containing SPL7013	VivaGel™	Phase I	Viral sexually transmitted diseases, formulated as a vaginal gel
Polymer–oligonucleotide conjugates			
PEG-aptamer	Macugen™	NDA filed	Age-related macular degeneration
Polymer–protein conjugates			
PEG-adenosine deaminase	Adagen®	Market	Severe combined immunodeficiency syndrome
SMANCS	Zinostatin Stimalmer®	Market	Cancer – hepatocellular carcinoma
PEG-L-asparaginase	Oncaspar®	Market	Acute lymphoblastic leukemia
PEG-α-interferon 2b	PEG-intron™	Market	Hepatitis C, also in clinical development in cancer, multiple sclerosis, HIV/AIDS
PEG-α-interferon 2a	PEGASYS®	Market	Hepatitis C
PEG-human growth hormone	Pegvisomant®	Market	Acromegaly
PEG-GCSF	Neulasta™	Market	Prevention of neutropenia associated with cancer chemotherapy
PEG-antiTNF Fab	CDP870	Phase II	Rheumatoid arthritis
Polymer–drug conjugates			
Polyglutamate-paclitaxel	CT-2103, XYOTAX™	Phase II/III	Cancer – particularly lung cancer
HPMA copolymer-doxorubicin	PK1; FCE28068	Phase II	Cancer – particularly lung and breast cancer
HPMA copolymer-doxorubicin-galactosamine	PK2; FCE28069	Phase I/II	Cancer – particularly hepatocellular carcinoma
HPMA copolymer-paclitaxel	PNU166945	Phase I	Cancer
HPMA copolymer camptothecin	MAG-CPT /PNU166148	Phase I	Cancer
HPMA copolymer platinate	AP5280	Phase II	Cancer
HPMA copolymer platinate	AP5346	Phase I	Cancer
Polyglutamate-camptothecin	CT-2106	Phase I	Cancer
PEG-camptothecin	PROTHECAN™	Phase II	Cancer
Polymeric micelles			
PEG-aspartic acid-doxorubicin micelle	NK911	Phase I	Cancer

results arising from trials with polymer–anticancer drug conjugates bodes well for future design and development of the ever more sophisticated bionanotechnologies needed to realize the full potential of the postgenomics age. Everyone uses water-soluble polymers, as an inert functional part of a multifaceted construct for improved drug, protein, or gene delivery.

Conceptually, polymer therapeutics share many features with other macromolecular drugs (proteins, antibodies, oligonucleotides) and macromolecular prodrugs including immunoconjugates. A bonus, however, is the versatility of synthetic chemistry, which allows tailoring of molecular weight, addition of biomimetic features to the man-made construct, and even the possibility to include bioresponsive elements.

2.4.1 Polymer–protein Conjugates

Recombinant DNA and monoclonal antibody technology has created a biotech revolution providing a growing number of peptide, protein, and antibody-based drugs. However, their limitations often include a short plasma half-life, poor stability and, for proteins, immunogenicity. Therefore, there has been a continuing search for improved protein-derived alternatives. In the 1970s, pioneering research of Davis, Abuchowski, and colleagues foresaw the potential of PEG conjugation to proteins. This technique is now well established and is called *PEGylation*. PEGylation is designed to increase protein solubility and stability, and reduce protein immunogenicity. Moreover, by preventing rapid renal clearance of small proteins and receptor-mediated protein uptake by cells of the RES, PEGylation can be used to prolong plasma half-life. The resultant need for less frequent dosing is of great benefit to the patient and encourages compliance.

PEG is a particularly attractive polymer for conjugation. It is widely used as a pharmaceutical excipient and the flexible highly water-soluble polymer chain extends to give a hydrodynamic radius that is some 5 to 10 times greater than that of a globular protein of equivalent molecular weight. There are three requirements for optimized synthesis of a polymer–protein conjugate: (1) a semitelechelic polymer, that is, with a single reactive group at one terminal end to avoid protein crosslinking during conjugation; (2) the ability to introduce a linker that will not itself generate toxic or immunogenic by-products and that will provide appropriate stability characteristics (dependent on the protein being bound); (3) and an approach that will provide reproducible site-specific protein modification. Linear and branched PEGs of Mw 5000 to 40 000 Da have been used to create protein conjugates, sometimes with multiple PEGs attached per protein, or alternatively a 1 : 1 ratio.

First-generation protein conjugates used linear monomethoxyPEGs (mPEG) and a variety of conjugation chemistries, but these early strategies had significant disadvantages including protein crosslinking (due to contaminating PEG-diol), modification of protein charge due to consumption of protein $-NH_2$ or $-COOH$ groups during conjugation, unstable PEG-protein linkages, and sometimes the need for reaction conditions that led to protein denaturation. More recently, improved conjugation techniques have been developed including site-specific modification following protein mutagenesis, the use of the enzyme transglutaminase to PEGylate site-specifically in the protein, and additionally, design of degradable PEG-protein

linkages to maximize return of protein bioactivity.

The clinical value of PEGylation is now well established (Table 6). PEG-L-asparaginase (ONCASPAR®) is used as treatment for acute lymphoblastic leukemia (ALL). Compared to the native enzyme, PEG-L-asparaginase brings advantages of reduced hypersensitivity, longer plasma half-life, and a slower total clearance. Consequently, it can be administered every two weeks instead of two to three times per week as required for the native enzyme. Most importantly, PEGylation of L-asparaginase decreases hypersensitivity reactions (only seen in ≤8% patients after conjugate administration). PEGylated-recombinant methionyl human granulocyte colony stimulating factor (G-CSF) is used to prevent severe cancer chemotherapy-induced neutropenia. Again, the PEG-GCSF (Neulasta™) has the benefit of less frequent administration being given by a single subcutaneous injection on day 2 of each chemotherapy cycle. The native G-CSF must be given daily for two weeks to achieve the same protection. Two PEG-interferon-α (IFNα) (2a or 2b) conjugates, PEGASYS® and PEG-INTRON®, have been approved as treatments for hepatitis C. Whereas IFNα-2a and IFNα-2b display similar biological activity and only differ in respect of a single amino acid, the molecular weight of PEG used for conjugation and the linker employed is very different in each product. PEGASYS® has a higher specific activity *in vitro* and a longer plasma half-life than PEG-INTRON®. Both conjugates have shown clinically superior antiviral activity compared to IFNα. PEG-IFNα is also under clinical evaluation for treatment of other diseases including, cancer, multiple sclerosis, and HIV/AIDS.

2.4.2 Polymer–drug Conjugates

In the 1970s, Ringsdorf first described the concept of targetable polymer–drug conjugates. These drug carriers have a tripartite structure comprising a water-soluble (hydrophilic) polymer backbone chosen to aid drug solubilization, a biodegradable polymer-drug linker designed to ensure stability in the circulation and subsequently facilitate drug release at the target site and, thirdly the inclusion of a targeting ligand to promote cell-specific delivery. A wide variety of natural, synthetic, and pseudosynthetic polymers have been explored as the platform, but so far those conjugates used clinically have only been based on *N*-(2-hydroxypropyl)methacrylamide (HPMA) copolymers, polyglutamatic acid (PGA), polyethyleneglycol (PEG) and polysaccharides derived from dextran (Table 6).

When selecting a polymeric carrier, a number of polymer features must be considered to ensure suitability for human use. The polymer should be nontoxic and nonimmunogenic. Preferably, the polymer backbone should be biodegradable, and if not (e.g. HPMA copolymers and PEG), the polymer molecular weight must be limited to <40 000 Da to ensure eventual renal elimination. To guarantee efficacy, the conjugate must have sufficient carrying capacity in relation to the potency of the anticancer drug to be carried. The first clinically tested polymer–drug conjugates all contained commonly used, and relatively potent, antitumour agents. The fundamental aim of polymer–drug conjugation is to modify pharmacokinetics at the cellular level and thus promote increased tumor targeting of drug while minimizing exposure of sensitive normal tissues. The polymer–drug linker must be stable in the circulation. At the cellular level, once internalized the conjugate is trafficked via

the endosomal compartments (acid pH 6.5–5.5) to lysosomes where it is exposed to both acid pH (~pH 5.0) and an array of lysosomal hydrolases.

The first polymer–drug conjugate to enter clinical trial did so in 1994; it was the HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin conjugate (PK1, FCE28068). It has an Mw ~30 000 Da and doxorubicin content of ~8.5 wt%. The peptidyl linker was designed to be cleared following lysosomotropic delivery by lysosomal cathepsin B. In Phase I trials, PK1 was administered as a short infusion every three weeks and the maximum tolerated dose was 320 mg m^{-2} (doxorubicin-equivalent). This is a ~fourfold increase compared to the normal safe dose of free drug and a higher dose than can be safely given in liposomal form. The dose-limiting toxicities seen were typical of the anthracyclines, including febrile neutropenia and mucositis. Despite cumulative doses up to 1680 mg m^{-2} (doxorubicin-equivalent), no cardiotoxicity, typical of anthracyclines, was observed. Antitumor activity seen in patients considered chemotherapy resistant/refractory and at lower doxorubicin doses (80–180 mg m^{-2}) was consistent with EPR-mediated targeting. Subsequently HPMA copolymer conjugates of paclitaxel, camptothecin, and platinates have also progressed into clinical trial. Despite a large number of studies exploring ligand-targeted polymer conjugates, an HPMA copolymer-Gly-Phe-Leu-Gly-doxorubicin containing additionally galactosamine (PK2, FCE28069) is still the only targeted conjugate to be tested clinically. It was designed to target the hepatocyte asialoglycoprotein receptor for treatment of liver cancer. Phase I/II trials were conducted in patients with primary hepatocellular carcinoma and the maximum tolerated dose was 160 mg m^{-2} Dox-equivalent. Although most of the conjugate localized in normal liver hepatocytes, it was estimated that the doxorubicin concentration in hepatoma tissue would still be 12 to 50-fold higher than could be achieved by administration of free drug.

Currently, a polyglutamic acid-paclitaxel conjugate (CT-2103, XYOTAX™) is showing considerable promise. This conjugate contains 37 wt% paclitaxel linked through the 2′ position of the ester bond to the γ-carboxylic acid of PGA (Mw ~40 000 Da). This is the first biodegradable polymer to be used for conjugate synthesis, and the polymer backbone is cleaved by cathepsin B to liberate diglutamyl-paclitaxel. When administered as a single agent intravenously over 30 min every 3 weeks, the maximum tolerated dose of CT-2103 was 266 mg m^{-2} paclitaxel equivalent. In these early trials, a significant number of patients have displayed partial responses or stable disease (mesothelioma, renal cell carcinoma, nonsmall cell lung cancer and a paclitaxel-resistant ovarian cancer patient) and the extensive Phase II and Phase III program now also includes combinations of CT-2103 with cisplatin and carboplatin.

2.5 Polymeric Micelles

Self-assembling block copolymer micelles provide an alternative targetable drug delivery vehicle. The most advanced example is the pluronic block copolymer micelle designed by Kataoka and colleagues incorporating doxorubicin (both covalently bound and noncovalently entrapped) that is able to circumvent P-glycoprotein-mediated resistance is currently in early clinical evaluation. The micelle is composed of PEG (Mw ~5000 Da)-poly(aspartic acid) block copolymers and has a diameter of 42 nm. Preferential accumulation in tumor tissue

by the EPR effect leads to a three- to four-fold improvement in drug targeting. In this case, the covalently bound drug is inactive, and it is the free drug that slowly escapes over 8 to 24 h that is responsible for tumor cell destruction.

2.6 Viral and Nonviral Vectors

The challenges of gene therapy are described in full elsewhere in this volume. However, as the natural (retroviral and adenoviral vectors are the favored tools for gene therapy) and synthetic nonviral vectors are being used as the new generation of targetable drug carriers, they are worthy of brief mention here. Viral vectors undeniably can circumvent all of the biological barriers to promote highly efficient gene delivery, and in certain cases show tissue tropism. However, viral vectors also have recognized disadvantages, in particular, their mixed safety record. The death of an 18-year-old patient in 1999 due to an acute inflammatory reaction after gene therapy, and the more recent observation that 2 of 10 children treated with gene therapy to correct severe combined immunodeficiency disease (SCID) developed a type of leukemia that was clearly caused by the viral vector, has led many to question the risk/benefit of this approach. While it is widely acknowledged that nonviral vectors offer potential advantages in terms of safety and ease of manufacture (and the lipidic-DNA complexes (lipoplexes) have been used in clinical trials), both lipoplexes and polymer-based delivery systems (polyplexes) are still far from ideal and there are many barriers to delivery. Their transfection efficiency is often extremely low and the most popular lipidic and polymeric vectors used are very toxic. Even with more than a decade of systematic study, so far all have failed to identify the ''ideal'' polymer construct that is able to promote efficient intracytosolic delivery of proteins and genes after repeated intravenous administration *in vivo*. Nonetheless, improving design of pH-responsive endosomolytic polymers gives hope that a synthetic viral mimetic will eventually become reality.

3 To the Future – The Importance of ''Nanomedicines''?

The challenges and opportunities of drug targeting have long been appreciated, and now, the first applications are at last coming to fruition, principally, but not exclusively, in the context of tumor targeting. This has spurred on the search for other targeting systems to localize drugs to sites of inflammation, to infectious diseases, to the brain, and to atherosclerotic plaques. There is increasing anticipation that nanotechnology, as applied to medicine, will bring still further advances in the diagnosis and treatment of disease. Within the confines of the nanoscale size range (1–1000 nm), the discipline of ''nanomedicine'' can be best defined as the science and technology of diagnosing, treating, and preventing disease and traumatic injury, of relieving pain, and of preserving and improving human health, using molecular tools and molecular knowledge of human body. It has five distinct, but overlapping subthemes. They include (1) analytical techniques and diagnostic tools; (2) nanoimaging and manipulations; (3) nanomaterials and nanodevices; (4) the *nanomedicines* designed either as biologically active therapeutics or drug delivery systems; and (5) all issues

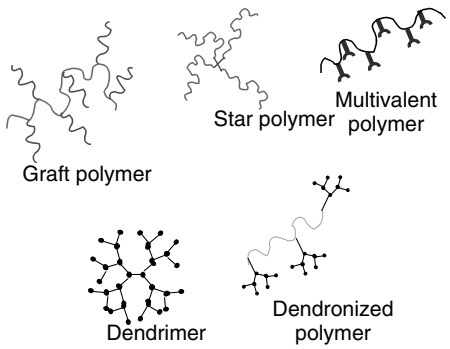

Fig. 9 The versatility of polymer chemistry can produce a range of polymer architectures now being used to develop second-generation drug targeting vectors.

relating to their pharmaceutical development; and clinical use with particular regard to potential toxicity.

The search for safe and effective targeted therapy continues in the postgenomics era, and as we understand more of the mechanisms of the disease progression and aging, ever more sophisticated diagnostics and therapeutics will undoubtedly emerge. In the long term, it is predicted that these activities will be combined, and the word ''theragnostic'' has been used to describe a system that is able to diagnose a problem and then deliver the therapy. Device miniaturization, with parallel efforts to bring together Mother Nature's molecules (as therapeutics and targeting ligands) and synthetic chemistry gives many exciting possibilities for designing novel therapeutics and targeting systems.

In the short term, research efforts are focusing on three main areas: (1) identification of new targets; (2) two-step approaches and combination therapy to increase specificity and efficacy; and (3) new vectors for improved targeting. Water-soluble synthetic polymers and polymer-based materials are playing an increasing role in drug delivery systems and biomaterial design. The search is on for new, safe, biodegradable polymers that are better suited to repeated parenteral administration, and also toward more elaborate 3D, bioresponsive architecture that bring the capacity to mimic the tertiary structure of proteins. A variety of architectures can now be synthesized and these are being used to create nanosized molecules with multifunctionality (Fig. 9).

Dendrimers and dendronized polymers are particularly interesting as they provide the multivalency needed for immobilization of drugs, imaging agents, peptidyl epitopes, and so on; they seem to offer unique opportunities for exploiting intracellular and transcellular trafficking pathways. Engineering shape memory into polymers has recently been described for polymer materials, and transfer of these concepts into water-soluble polymer architecture, perhaps using molecular imprinting techniques, remains an exciting challenge for the future.

Keywords

dNTP
Deoxyribonucleoside triphosphate.

rNTP
Ribonucleoside triphosphate.

RT–PCR
Reverse transcription–polymerase chain reaction.

Telomerase
The ribonucleoprotein enzyme that synthesizes telomeric DNA.

Telomeres
Essential genetic elements at the termini of linear chromosomes.

Telomerase Primer
An oligonucleotide, typically a telomeric DNA sequence, capable of being extended by telomerase.

TERT
Telomerase catalytic protein.

TR
Telomerase RNA subunit.

Immortal cells transmit essentially a complete genome from one division to the next. To ensure the full replication of their DNA, most immortal eukaryotic cells possess a unique enzyme, telomerase, which apparently evolved with the ends of linear chromosomes, specifically for the *de novo* synthesis of telomeric DNA. Telomere maintenance is the only known biochemical function of telomerase, and in the absence of telomerase, telomeric DNA is gradually lost with each round of cell division. Normal human somatic cells are considered mortal since they have a finite capacity for division. The observation that normal cells lack telomerase, while most tumor cell populations express telomerase, suggests an important biological function for this enzyme in controlling a key difference between mortal and immortal cells.

1
Telomerase and Telomere Maintenance

Telomeres are DNA-protein structures that cap the ends of eukaryotic chromosomes and have a distinctive chromatin organization. Telomeric DNA is noncoding and consists of tandem reiterations of simple G-rich repeats oriented 5′ to 3′ toward the chromosome termini and overhanging the C-rich strand (Fig. 1). The second component of telomeres are proteins that bind to telomeric DNA in a sequence-specific manner or through protein–protein interactions. In some species, the DNA terminus is folded back into a loop structure (t-loop) stabilized by telomeric proteins. Both DNA and protein components are required for telomere function. Telomeres are essential for chromosome stability and function because they prevent nucleolytic degradation and fusion of chromosome ends, contribute to chromosome movement and localization within the nucleus through their attachment to the nuclear matrix, and can affect gene expression through position effects. Moreover, telomeric DNA contributes to the complete replication of the chromosome. Since eukaryotic DNA polymerases catalyze synthesis only in the 5′ to 3′ direction and utilize an RNA primer for initiation, linear DNA molecules cannot be replicated in their entirety (Fig. 2). Telomeric DNA shoulders the loss of terminal sequences masked by the 5′-most primer, thus acting as a buffer against loss of internal and essential genes. In addition, being subject to elongation by telomerase, telomeric DNA provides a means for compensating for the loss of sequences stemming from the end replication problem.

Telomere length is extremely variable among species, possibly as a result of differences in minimal functional sizes that may reflect the number of telomeric proteins or protein-binding sites. In addition, there is marked heterogeneity in telomere length among chromosomes of individual cells, probably due to unequal loss and/or synthesis of telomeric DNA.

2
Telomerase Biochemistry

2.1
Telomerase: A Novel RNA-dependent DNA Polymerase

Telomerase activity was first discovered in the ciliate *Tetrahymena thermophila* on the basis of its novel property of extending a telomere-like oligonucleotide with *de novo* synthesized telomeric DNA. The enzyme is a ribonucleoprotein comprising a structural RNA molecule and a catalytic

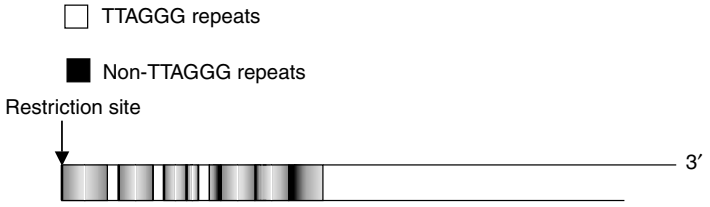

Fig. 1 Structure of terminal restriction fragments: digestion of genomic DNA with restriction enzymes releases terminal restriction fragments (TRFs) comprising a telomeric region of perfect TTAGGG repeats, and a subtelomeric region containing degenerate TTAGGG repeats, possibly interspersed with perfect repeats and unrelated simple sequences.

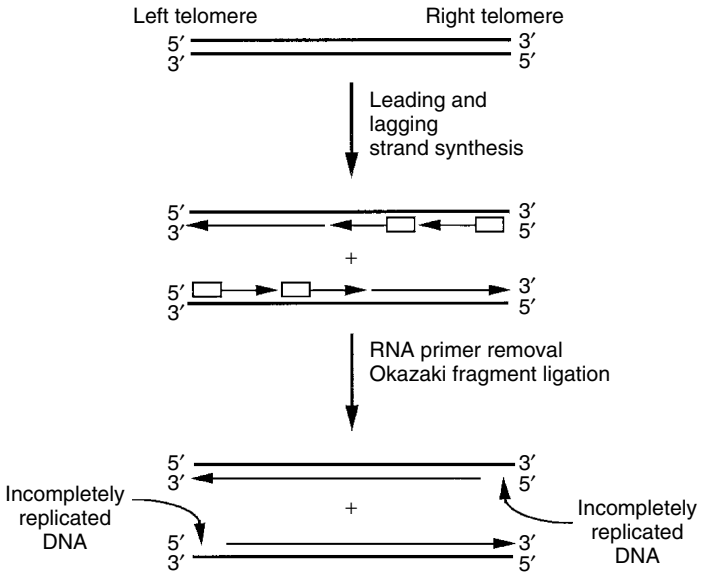

Fig. 2 The end replication problem: DNA polymerases synthesize DNA in the 5′ to 3′ direction and require an RNA primer (open boxes) for initiation of synthesis. Synthesis of the lagging strand is discontinuous and generates Okazaki fragments that are ligated to one another following removal of primers and new DNA synthesis. Removal of the 5′-most primer results in an irreparable gap at the 5′ end of the molecule. Thus, the daughter strand is shorter than the parental strand at this point. The extent of sequence loss reflects the size and position of the 5′-most primer; since the latter may vary, daughter molecules of different length may be generated.

protein. In yeast and human, the enzyme is a dimer of the two core components. A short region of the RNA subunit, called the *template domain*, is complementary to the species-specific telomere sequence and directs the synthesis of the proper telomeric DNA (Fig. 3). Thus, telomerase functionally is a reverse transcriptase: an RNA-dependent DNA polymerase. However, unlike viral reverse transcriptases that can fully copy varied ''exogenous'' RNAs, telomerase utilizes only a small template domain of its specific integral RNA. Most telomerases are processive and capable of reiteratively copying the template region without dissociating from the extended DNA chain. Thus, after binding to a DNA primer (typically a telomere sequence), telomerase cycles between an elongation phase in which deoxyribonucleotides (dNTPs) are sequentially added to the 3′ end of the DNA, and a ''translocation'' event, in which telomerase advances one repeat relative to the telomere (Fig. 3). The reiterative copying of the template domain accounts for the simple repeated structure of telomeric DNA at chromosome ends of most eukaryotic species.

2.2 Functional Sites and Catalytic Activity

The template region of the integral RNA component of telomerase typically

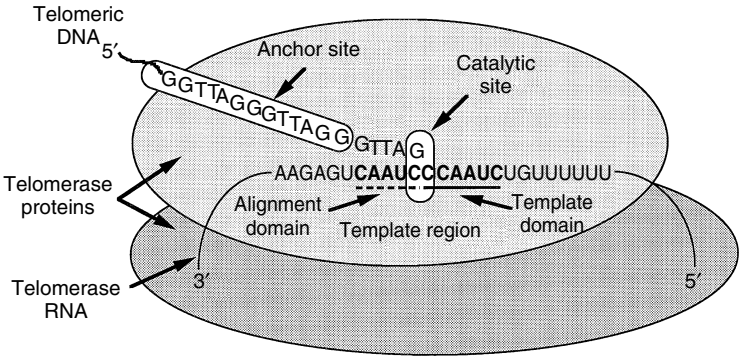

Fig. 3 The template region and primer-binding site of human telomerase: the presumed primer template configuration at the catalytic site of human telomerase is schematically illustrated, along with functional sites within the protein components (shaded ovals) and the RNA template region. This picture captures the relative position of telomeric DNA and the template region just after a translocation event: the 3′ end of the DNA is positioned opposite the alignment domain of the RNA template region, with the catalytic site ready to add dNTPs according to the sequence dictated by the template domain.

contains more than one repeat of the complementary telomeric sequence. The additional bases at the 3′ side of the template domain are utilized in part as an ''alignment domain'' to facilitate the binding of DNA to telomerase. This binding and alignment is especially important following the translocation event when the 3′ end of the DNA slips back such that it is entirely outside the template domain (Fig. 4). However, RNA:DNA hybridization is not sufficient to account for binding of the DNA primer to telomerase. An ''anchor site'' involving protein–DNA interactions also functions in initial primer binding as well as in maintaining the correct position of the DNA during the elongation/translocation events.

The anchor site of telomerase is somewhat promiscuous in that it is capable of utilizing various DNA sequences as primers for telomere extension. Telomerase can also utilize an RNA primer under certain circumstances and even incorporate ribonucleoside triphosphates (rNTPs) when they are present at high concentrations in the absence of the correct deoxyribonucleoside triphosphates (dNTPs). However, only dNTPs complementary to the template bases are efficiently added to the growing DNA primer. Nontelomeric primers that function in a telomerase assay are generally relatively G-rich single-stranded DNAs and typically have a 3′ end with some similarity to the natural telomere sequence. This suggests that the anchor site has some affinity for exposed guanine bases and that hybridization of the 3′ end of the DNA primer to the alignment region is important in forming a proper primer:template configuration. With the 3′-OH of the primer positioned in the catalytic site of the enzyme, formation of the phosphodiester bond catalyzed by all nucleic acid polymerases can occur between the terminal 3′-OH and the α-phosphate of the incoming dNTP, which is selected on the basis of its complementarity to the template ribonucleotide in the catalytic site at that time. No additional high-energy bond cleavage other than that of the dNTPs appears to be necessary for

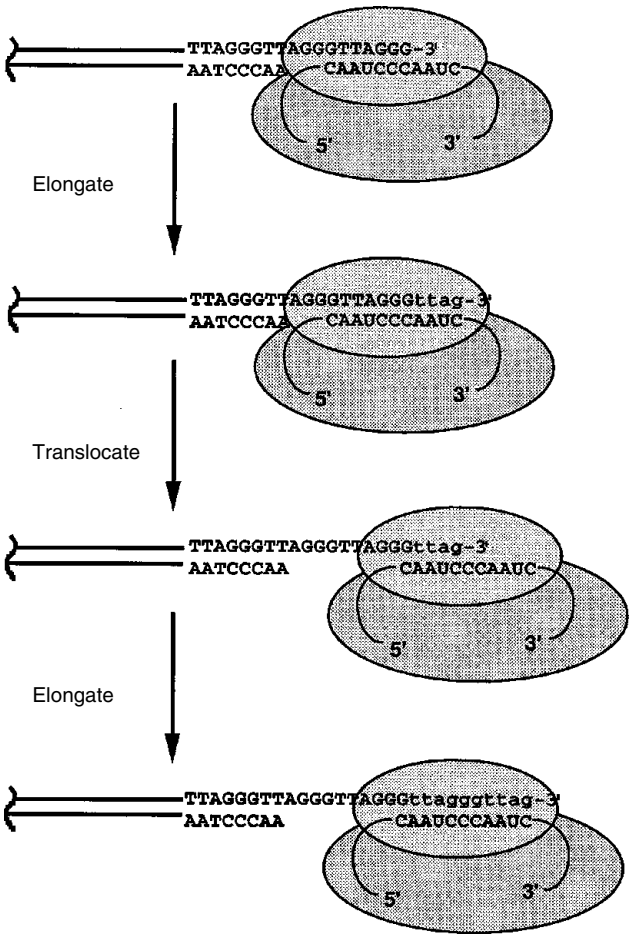

Fig. 4 Telomerase mechanism of action: the spatial relationships between telomerase protein subunits (shaded ovals), telomerase RNA (curved strand showing the human template region, CAAUCCCAAUC), and the end of a human chromosome during the cyclical process of elongation and translocation.

elongation and translocation. It is possible that translocation is facilitated by two additional properties of telomerase: a helicase-like activity that maintains a small number of base pairs between the growing DNA chain and the template, and a potential strain, which builds during the elongation steps when the relative position of the RNA and the catalytic site of the proteins must gradually change.

2.3 Telomerase Components

2.3.1 Telomerase RNA Component

The RNA subunit of telomerase (TR) has been characterized in numerous organisms including humans (Table 1). All TRs contain a region comprising the alignment and template domains whose functional role has been demonstrated by

Tab. 1 Some known telomerase RNAs.

Species[a]	*Telomere repeat*	*RNA size (nucleotide)*	*Template region (3′ to 5′)*[b]
Human	GGTTAG	~450	CAAUCCCAAUC
Mouse	GGTTAG	~450	AUCCCAAUC
T. thermophila	GGGTTG	159	AACCCCAAC
O. nova	GGGTTTTG	190	CCAAAACCCCAAAAC
E. crassus	GGGTTTTG	189	CCAAAACCCCAAAAC
S. cerevisiae	$(TG)_{1-3}\ TG_{2-3}$	~1300	CACCACACCCACACAC

[a]Complete cDNAs for the RNA components have been published for human, mouse, *Tetrahymena thermophila*, *Oxytricha nova*, *Euplotes crassus*, *Saccharomyces cerevisiae*, and a number of other ciliates and yeast species.
[b]The putative template domain of the template region is underlined. The degenerate telomere sequence of *S. cerevisiae* can be explained by variable alignment of the telomeric DNA 3′ end on the template region and/or variable sites of termination during elongation.

site-directed mutagenesis. However, TRs from different species are highly divergent both in size (150–1300 nucleotides) and primary sequence. In addition, there are significant differences in their biogenesis: ciliate TRs have a polyU, are transcribed by DNA polymerase III, and matured through pathways specific for polIII transcripts, whereas vertebrate and yeast TRs are transcribed by DNA polymerase II and have a TMG cap. Mammalian TRs belong to the family of small Cajal bodies RNA (scaRNAs) and may be matured and/or assembled into these structures.

On the other hand, eukaryote TRs show a high degree of similarity in the secondary structure with a core that includes the template region and a pseudoknot motif (Fig. 5). The latter is important for the interaction of TR with the catalytic protein TERT, for the assembly of an active telomerase *in vivo* and for enzyme processivity and dimerization. An additional structural element upstream of the template in all TRs is the 5′ template boundary, which is important to prevent telomerase from copying beyond the template sequences. The mechanism that defines the template boundary varies among different species being based on a specific sequence in ciliates, a helix (helix 1) in yeast, or a helix (P1b) or sequence in vertebrates. The boundary element in most TRs represents also a site of high affinity interaction with the telomerase catalytic subunit.

Outside the template/pseudoknot core element, the secondary structure of TRs is less conserved. In ciliate TRs, a stem-loop element, called helix IV, binds TERT, is important for telomerase processivity, and for the formation of the pseudoknot. Vertebrate TRs contain a highly conserved region, CR4/CR5, which is crucial for telomerase function. Within this region are the P6.1 stem, which has been implicated in hTR binding to hTERT, and the P6.1 loop, which is important for catalytic activity. The main distinctive characteristic of vertebrate TRs is the catalytic subunit binding site, which includes two elements, the pseudoknot and the P6.1 stem, which are far away

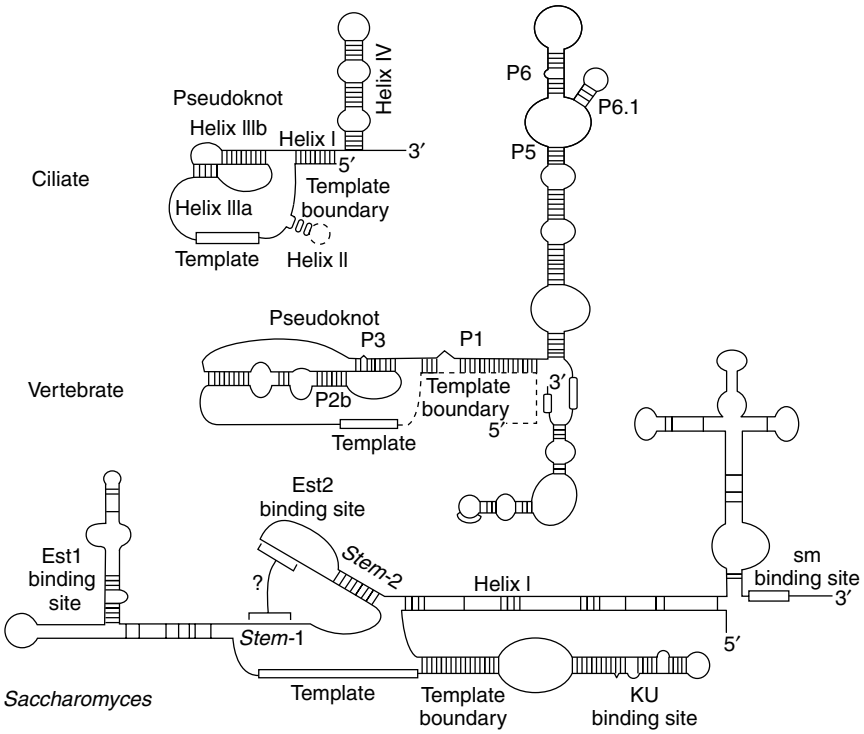

Fig. 5 Secondary structures of ciliate, vertebrate, and yeast (*Saccharomyces*) telomerase RNAs. The structures that are present in some but not all species within a group are represented by dashed lines. Conserved regions that bind to TERT are in green; structures defining the template region are in red, and those defining the template boundary are in blue. Reprinted from Chen, J.-L., Greider, C.W. (2004a) An emerging consensus for telomerase RNA structure, *Proc. Natl. Acad. Sci. U.S.A.* **101**, 14683–14684. With permission. (See color plate p. xxiii.)

from each other in the primary sequence, whereas ciliate and yeast TRs bind the catalytic subunit through the pseudoknot and the immediately adjacent stem-loop element.

The most divergent region among TRs is the 3′ region, which is essential for TR maturation and stability. Yeast TR contains a structural element that acts as a binding site for Sm proteins, which are involved in the maturation of snRNA and are required for efficient TR biogenesis. In vertebrate TRs, the 3′ portion contains two elements that are essential for stability and maturation, the H/ACA box and the CR7 domain. The H/ACA motif is usually found in small nucleolar RNAs (snoRNAs) involved in the posttranscriptional modification of rRNA. Among the proteins that bind to this motif is dyskerin/Cbf5p (see the following). The CR7 motif is a telomerase-specific stem-loop motif, which contains a localization signal specific for Cajal bodies (CAB motif), intranuclear structures where snRNAs and snoRNAs are matured and modified. Yeast TRs contain two additional structural elements not conserved in other TRs: the Ku-interacting stem-loop and the Est1p-interacting motif.

2.3.2 **Telomerase Protein Component**

The telomerase protein (TERT) is the rate-limiting determinant of enzymatic activity. The protein has at least three functions: binding the template RNA, binding DNA, and catalyzing the elongation/translocation events. Telomerases from ciliates, yeast, and humans have also a cleavage activity capable of removing the terminal nucleotide of the DNA extension product at the pause site (i.e. when the extension product is at the 5′ end of the template domain). The TERT gene has been cloned from several species from ciliates to mammals, including humans (Table 2). In essentially all cases there is a single gene encoding a protein of 100–130 kDa that is phylogenetically conserved. The TERT proteins belong to the family of reverse transcriptase with which they share a set of motifs (RT). In addition, all TERTs contain a unique T motif (T) and ciliate TERTs also contain a unique CP motif (Fig. 6). Mutational analysis has mapped the catalytic core of the enzyme within the RT domain; mutations of the T motif also abolish or reduce activity. In addition, amino acid residues at the N and C terminus are important for TR binding, nuclear or nucleolar localization, multimerization and activity. Among the latter there are residues that dissociate catalytic activity, as assayed *in vitro*, from telomere maintenance *in vivo*.

Regulation of telomerase has been extensively characterized in humans. The hTERT gene maps on the short arm of chromosome 5, is over 40 kb in size and comprises 16 exons and 15 introns (Fig. 7). The gene is alternatively spliced and several different transcripts are differentially expressed during embryonic

Tab. 2 Some cloned TERTs.

Species	***Gene # introns***	***Protein***	
		Size [kDa]	***PI***
Human	15	127	11.3
Mouse	>11	127	10.3

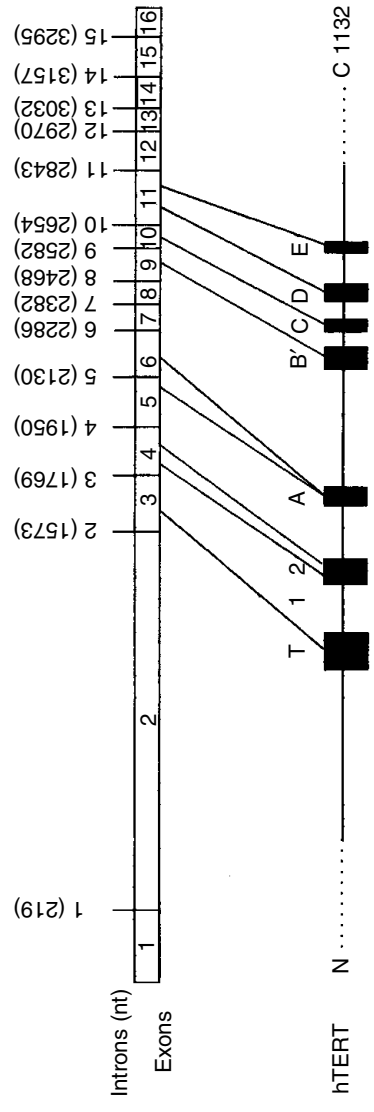

Fig. 7 Organization of the hTERT gene. Introns and exons are indicated. Numbers in brackets refer to the nucleotide position of the intron with nt 1 being the A of the ATG. The location of the telomerase-specific T motif and of the RT motifs and their assignment to exons encoding them is indicated. Reprinted from Cong, Y.S., Wen, J., Bacchetti, S. (1999) The human telomerase catalytic subunit htert: organization of the gene and characterisation of the promoter, *Hum. Mol. Genet.* **8**, 137–142. With permission.

development and are present in somatic cells. Spliced transcripts are not associated with enzymatic activity, but the product of the α splice variant has been reported to inhibit the enzyme when exogenously expressed in cells. It is, however, unclear whether alternative splicing contributes to regulation of hTERT expression.

Telomerase activity and expression of hTERT full-length mRNA disappears during embryonic development and remains absent in most adult somatic tissues. Transcriptional regulation appears to be the process primarily responsible for this phenomenon. The hTERT promoter has been cloned and characterized. It has no TATA or CAAT boxes but contains a large CpG island around the ATG. Promoter methylation, however, does not appear to play a major role in the control of hTERT expression. The minimal promoter, as determined by deletion analysis, spans 330 bp upstream of the ATG but regulatory sequences that may be essential *in vivo* extend further upstream for up to at least 7 kb. The hTERT promoter contains binding sites for many transcription factors several of which have been shown capable of activating (e.g. c-Myc, Sp1) or repressing (e.g. Mad1, p53) hTERT gene expression. The abundance of these sites has suggested that regulation of hTERT expression may operate at multiple levels and/or involve different factors in different tissues. This hypothesis is supported by the observation that transcriptional repressors of telomerase, mapping on different human chromosomes, are differentially active in different cell contexts. Activation of telomerase can also been induced by steroid hormones and the HPV16 E6 protein, while pRB, E2F, and the Wilms' tumor 1 tumor suppressor can repress hTERT transcription. Regulation of telomerase expression may also involve modification of the local chromatin structure through the recruitment by transcription factors of histone acetyltransferases or deacetylases on the hTERT promoter.

Posttranslational modifications, primarily phosphorylation, of the hTERT protein may represent an additional level of control for expression of the enzyme. Phosphorylation by PKC-α and ζ and by Akt has been reported to enhance enzyme activity, while phosphorylation by the tyrosine kinase c-Abl represses it. In addition, phosphorylation has been implicated in the translocation of hTERT from the cytoplasm to the nucleus where it can catalyze telomere elongation.

Lastly, in tumors cells, which are usually telomerase positive (see the following), supernumerary hTERT genes due to chromosome 5 polysomy may contribute to the upregulation of hTERT expression.

2.3.3 Telomerase-associated Proteins

The telomerase complex is larger than the sum of the two core components, TR and TERT, and varies in size in different organisms. Several proteins have been identified as components of the telomerase holoenzyme, and many have been implicated in regulating the function and/or the assembly of the complex. For some, however, the biological function has not been identified.

In the ciliate *T. thermophila* two proteins, p80 and p95, copurify with telomerase activity. Although not essential for catalysis, they act as negative regulators of telomere length. Two additional telomerase-associated proteins, p45 and p65, have been characterized in *Tetrahymena*. Both proteins appear involved in telomere length regulation since their absence results in telomere shortening. p65 interacts with TR and shares a La motif with the *Euplotes aediculatus* protein p43

and the mammalian La antigen, which are also associated with telomerase and are likely to be involved in telomere length regulation.

In *Saccharomyces cerevisiae*, two proteins, Est1p and Est3p, are important for telomerase activity *in vivo*: deletion of either of them causes telomere shortening without affecting catalytic activity *in vitro*. The specific role of these proteins is still under investigation, but the available data are consistent with a role of Est1p in the recruitment of telomerase to the telomere through its interaction with TR and the complex Cdc13p/Ten1/Stn1, which binds to the single-stranded telomeric end. Some data also suggest that Est1p may participate in the activation of the telomerase complex at the telomeres. Est3p is known to associate with the telomerase subunits, but its function is still unknown. The telomerase complex in yeast also includes the heterodimer yKu70/80, which binds TR. Ku, a major component of the nonhomologous end joining (NHEJ) pathway activated in response to double-strand DNA breaks, binds chromosome ends and contributes to telomere length regulation and end protection. In addition, Ku, together with other telomere-binding factors, such as Cdc13p, plays a role in facilitating telomerase action at telomeres, suggesting that its functions in telomere biology are complex.

Cdc13p, a single-strand DNA binding protein with high specificity for the telomeric repeats, plays a major role in telomere maintenance in yeast. Its function is regulated by two binding partners, Stn1p and Ten1p. The complex Cdc13/Ten1/Stn1 is required for telomere end protection, as well as for telomere replication through the recruitment of telomerase. Data from several laboratories support a dual role for Cdc13p: (1) recruitment of telomerase to the telomeres, through Est1p, thereby allowing elongation of chromosome ends, and (2) involvement in C-strand synthesis together with Stn1p, thereby limiting further elongation.

The vertebrate protein TEP1 (telomerase associated protein 1), is the homolog of *Tetrahymena* p80. The N terminus of TEP1 interacts with TR; in addition, the protein contains a C-terminal protein–protein interaction motif (WD40 repeats) that may mediate its association with TERT. The function of TEP1 is still unclear: removal of the protein from the telomerase complex in mice has no effect on telomerase activity or telomere length.

The organization of the telomerase complex in vertebrates shares some similarities with that of yeast, although not all proteins are common to the two organisms. Among hTERT-interacting proteins are the molecular chaperones p23 and hsp90, essential for assembly and activity *in vivo*, and the SMN (survival of motor neuron) protein, which may be involved in localization of telomerase to nucleoli and/or Cajal bodies. Nuclear retention of telomerase appears to require the 14-3-3 protein to which hTERT binds through its C terminus. More recent data have shown that an RNA chaperone, nucleolin, interacts with telomerase and regulates its subcellular localization, although it is not clear whether the protein participates in telomerase assembly or acts as a reservoir of active enzyme in the cell. Two other proteins interacting with hTERT *in vitro* and *in vivo* are EST1A and EST1B, putative human homologs of yeast Est1p. For EST1A, there is experimental evidence for its involvement in telomere capping and telomere length regulation. Both hTERT and hTR interact *in vitro* with PINX1, a TRF1 binding protein, which acts as a negative regulator of the activity. *In vivo* the interaction of PINX1

with telomerase depends on hTERT and involves the hTR-binding domain of this subunit. Among proteins that interact with hTR, dyskerin and its family members Nhp2, Nop10, and Gar1 are important for hTR accumulation, stability, and maturation; hStau and L22 are involved in telomerase localization, and the La antigen plays a yet undefined role in telomere length determination. Lastly, hnRNP proteins A1, C1/C2, and UP1 have been implicated in the regulation of telomerase access to telomeres through their interaction with both hTR and telomeric DNA.

In human cells, a similar role to that of Cdc13p has been proposed for POT1 (protection of telomeres 1). Like Cdc13p, POT1 is a single-strand DNA binding protein with high affinity for telomeric DNA and belongs to the family of DNA binding proteins containing an OB fold (oligonucleotide binding) DNA binding domain. In human cells, POT1 is recruited to the telomeres through the TRF1 complex and has been involved in telomere length regulation. Moreover, the data available so far suggests a possible involvement of POT1 in end protection and in regulating telomerase recruitment and/or activation at the telomeres. Access of telomerase to its telomeric DNA substrate is also dependent on telomeric proteins (e.g. TRF1 and TRF2 in mammals) that stabilize the t-loop structure of telomeres.

3 Telomerase Assays

3.1 Biochemical Assays

3.1.1 The Standard Assay

The standard telomerase reaction uses a telomeric oligonucleotide, such as $d(TTAGGG)_3$ for the human enzyme, as the primer for extension by telomerase in a cell-free extract mixed with appropriate buffers and deoxyribonucleotides. Most of the telomerase activity from mammalian cells resides in the supernatant (i.e. ''cytoplasmic fraction'') from a 100 000 xg centrifugation (the ''S100'' fraction) of either mechanically ruptured or detergent-treated human cells. Since telomeres reside in the nucleus of a cell, it is assumed that most telomerase *in vivo* would be found in the nucleus and that the enzyme may leak from this compartment during preparation of the extract.

The products of the telomerase reaction in a cell-free extract can be labeled by the incorporation of $[\alpha^{32}P]$ dGTP during elongation of the primer and then detected by autoradiography after resolution of the products on a polyacrylamide gel. In the case of human telomerase, which is processive and reiteratively copies the six-nucleotide template in a cyclical fashion, the products of the many simultaneous extension reactions occurring in the test tube generate a ''ladder'' of bands spaced at a six-nucleotide distance (Fig. 8). Moreover, the generation of this characteristic ladder is sensitive to pretreatment of the extract with RNase, since telomerase utilizes its integral RNA as the template for telomere synthesis. Thus, a ''+RNase'' reaction is often included as a negative control in telomerase assays.

3.1.2 TRAP: Telomere Repeat Amplification Protocol

A highly sensitive and reproducible assay for telomerase utilizes a polymerase chain reaction (PCR) step to amplify the telomerase products prior to detection. Modifications to the reaction conditions for the telomerase portion of this ''telomere repeat

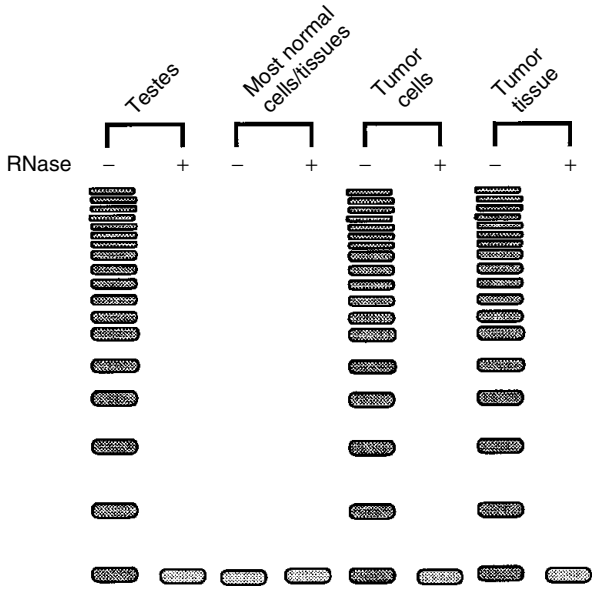

Fig. 8 A standard telomerase "ladder": gel electrophoresis of telomerase products resolves the DNA oligonucleotides according to size. Since the translocation event is slow relative to elongation, there is a greater frequency of partial products at six-nucleotide intervals corresponding to the extension products that reach the 5' end of the template domain. In telomerase-positive tissues such as testes, tumor cells in culture, or tumor biopsies, a distinct ladder of products is seen. This pattern is not seen when the extract is pretreated with RNase, since RNase destroys telomerase activity.

amplification protocol," or TRAP, streamline the overall assay and reduce the chance of PCR artifacts. A critical modification is the use of a non-TTAGGG oligonucleotide (TS), which acts as a good primer for telomerase but reduces the probability of primer/dimer artifacts during the PCR amplification step. The C-rich complementary primer for the PCR reaction is also changed from the perfect CCCTAA repeat to reduce the possibility of false-positive products in the PCR phase of the assay, which may be generated by primer/dimer formation. TRAP is more reliable and sensitive than the standard assay and is capable of detecting telomerase activity in as few as 10–100 telomerase-positive cells among 10^5–10^6 telomerase-negative cells. Thus, very small tissue samples can be analyzed for the presence of positive cells. Detection systems can use either radioactivity or stains incorporated or intercalated into the double-stranded DNA created by the PCR reaction. Fresh or frozen biopsy, autopsy, and surgical specimens, including frozen histological sections, can be analyzed for telomerase activity with TRAP. TRAP, however, is an activity assay and thus cannot be used on fixed material or on poorly stored or necrotic material in which enzyme activity is compromised. To avoid false negatives, tissues should also

be tested for the presence of inhibitors of telomerase or Taq polymerase by mixing or titration experiments.

3.2 Expression Assays

Unlike the RNA component, which is expressed ubiquitously, the telomerase catalytic protein is rate limiting for enzymatic activity and is expressed only in telomerase-positive cells. Detection of the enzyme, therefore, can be achieved by reverse transcription–polymerase chain reaction (RT–PCR) with primers specific for the telomerase mRNA, or by immune reactions using antibodies against the protein component.

4 Telomeres, Telomerase, and Cell Life Span

In multicellular eukaryotes, reproductive cells have unlimited proliferative potential (immortality), whereas somatic cells are capable of only a limited number of divisions. The finite replicative capacity of normal somatic cells has been termed *cellular senescence* and is believed to play a significant role in age-related disease.

It has been proposed that the proliferative capacity of somatic cells is at least partly controlled by the status of their telomeres and telomerase (Fig. 9). In the absence of the enzyme or of any mechanism for telomere maintenance, the loss of telomeric DNA that occurs with each round of replication is thought to act as a ''mitotic clock'' that registers the number of times a cell has divided and signals cessation of division (senescence), presumably when one or more telomeres have attained a functionally suboptimal size or structure. Somatic telomere length, therefore, may be both an indicator of the cell proliferative history and a predictor of its replicative potential. In accord with this model, sperm and ova express telomerase activity and maintain telomere length from one generation to the next. At least in humans, somatic cells have little or no telomerase activity and contain telomeres that are progressively shorter with donor age or cell division in culture. This pattern of telomerase expression is consistent with somatic repression of the enzyme. Telomerase repression in humans appears to be part of an early developmental program, since activity has been detected in certain fetal tissues, whereas, no or little activity is detectable in the corresponding tissue from young postnatal or adult donors. The stringency of telomerase repression is greater in humans than in rodents since telomerase can be easily detected in several adult mouse tissues.

5 Telomerase and Human Disease

5.1 Cancer

Escape from cell senescence and ultimately the immortalization of somatic cells are believed to be important aspects of tumorigenesis. Thus, repression of telomerase and cell senescence can be viewed as tumor suppressor mechanisms. The difference in telomerase regulation between humans and rodents may in part account for the much higher frequency of spontaneous cell immortalization and cancer in rodents compared to humans.

The role of telomerase in human cancer is supported by numerous data indicating that telomerase is reactivated upon cell immortalization *in vitro* (Fig. 9) and is present in the vast majority of tumor-derived cell lines and of tumor tissues

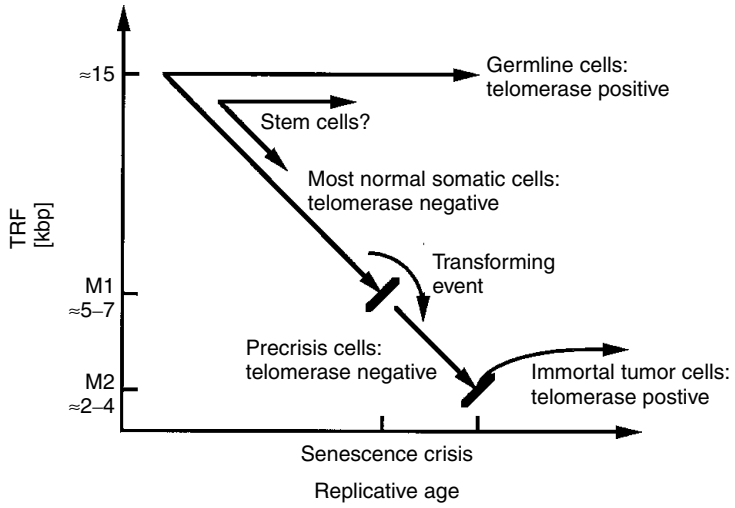

Fig. 9 The telomere hypothesis: reproductive cells, and perhaps stem cells, express telomerase activity and maintain stable telomeres. During development, telomerase is repressed in most somatic cells and, as a consequence, telomeres shorten with cell division. Shortening of telomeres is thought to monitor the proliferative history of somatic cells and to signal growth arrest (senescence) when telomeres have reached a functionally suboptimal size. Transformation extends the proliferative capacity of cells but does not reactivate telomerase, and transformed cells continue to lose telomeric DNA till the end of their extended life span (crisis). At crisis, telomeres on average are extremely short and some may be absent, and chromosomes become unstable. The loss of cell viability occurring at this stage may be due to nonfunctional telomeres and/or lethal chromosome aberrations resulting from terminal fusion of unprotected chromosomes. The rare cells that reacquire telomerase activity have stable telomeres and are immortal.

(Table 3). Indeed, telomerase rates as the most prevalent tumor marker described to date, and it is assumed that enzymatic activity signifies the existence of at least a subset of immortal cells in the malignant tissues. The apparent lack of telomerase in most somatic tissues and its widespread presence in malignant tissues has raised the hope that inhibition of enzymatic activity may be exploited in the management of cancer. Such inhibition should lead to loss of cell viability through resumption of telomere shortening. *In vitro* experimental data from lower eukaryotes and from human cells support this expectation: deleting the telomerase gene or inhibiting telomerase biogenesis by the antisense transcript of the template RNA or of the TERT mRNA can restore a mortal phenotype to otherwise immortal cells by causing telomere loss, and ultimately senescence or crisis of the cell population (Fig. 9). There are, however, several issues to be addressed before it may be possible to validate this approach for clinical treatment. Reagents that inhibit telomerase efficiently and specifically are not yet available. In addition, the biological outcome of telomerase inhibition on normal and malignant tissues *in vivo*

has yet to be investigated. Relevant to this issue is the existence of alternative mechanisms of telomere maintenance that may become active in transformed cells upon telomerase inhibition.

Last, the nearly ubiquitous presence of telomerase in tumors suggests that the enzyme should also serve as a diagnostic or prognostic marker for cancer. Telomerase activation in cancer does not appear to be associated directly with deregulation of growth or metastatic capacity. Thus, in the multihit process of tumorigenesis, there should be no direct selective advantage for telomerase activation until the tumor cells have reached crisis with critically short telomeres. The early events in tumorigenesis likely involve activation of proto-oncogenes and inactivation of tumor suppressor genes that confer various forms of growth advantage during successive rounds of clonal expansion and selection in the tumor population. Telomerase activation is, therefore, expected to be a late event in most cancers and would correlate with relatively aggressive forms of the disease.

5.2 Age-related Diseases

Genetic ablation of the TR gene in mice, which retain telomerase expression in adult somatic tissues, leads to age-related pathologies. Conversely, exogenous expression of hTERT in telomerase-negative normal human cells in culture extends their life span without acquisition of a transformed phenotype. Reactivation of the enzyme in a transient or regulated manner could theoretically be used to extend the replicative life span of somatic cells, particularly in the case of premature aging syndromes or in aging tissues of otherwise healthy individuals. There are a number of tissues in which replicative cell senescence may play a role in the pathology of age-related diseases. Examples include senescence of dermal fibroblasts in skin aging (decreased wound repair and susceptibility to ulcers), senescence of endothelial cells in vascular aging (cardiovascular diseases), senescence of osteoblasts in bones (osteoporosis), and senescence of lymphocytes in peripheral blood (susceptibility

to infection). An alternative to telomerase reactivation for increasing cell life span is intervention through any mechanism that slows the rate of telomere loss in telomerase-negative tissues, for example, mechanisms that counteract the enhanced rate of loss caused by oxidative stress.

5.3 Dyskeratosis Congenita

In addition to cancer, a human genetic disease, Dyskeratosis congenita (DC), has been linked to telomerase. DC is a rare inherited multisystem disease that targets highly regenerative tissues and results in bone marrow failure. The autosomal dominant form of DC is characterized by mutations in hTR, suggesting that defects in telomerase function may influence the DC phenotype. Indeed, in affected families the disease shows anticipation and correlates with the presence of shorter telomeres. Most mutations found in patients affected by autosomal dominant DC occur in regions of hTR that are important for either catalytic activity or RNA stability. Recent data both *in vitro* and *in vivo* suggests that the clinical manifestations of autosomal dominant DC may be caused by telomere shortening due to lack of activity or haploinsufficiency of telomerase.

Keywords

Chromatin Immunoprecipitation (ChIP)
Living cells are fixed with formaldehyde, and cell extracts are prepared. Specific protein–DNA complexes are precipitated by immunoprecipitation and the associated DNA is purified and amplified by PCR (polymerase chain reaction) with specific primers.

Fission Yeast Telomere and Telomeric G-rich Overhang
Telomere DNA comprises specific G-rich tandem repeat sequences. The consensus sequence of fission yeast telomeric repeat is TTACAGG. The average length of fission yeast telomeric repeats is 300 bp. Although telomeric repeat sequence and telomere

Encyclopedia of Molecular Cell Biology and Molecular Medicine, 2nd Edition. Volume 14

ISBN: 3-527-30651-X

length vary, the structure of the very end of the telomere is conserved among species. The G-rich strand protrudes as a 3′ single-strand overhang.

Life Cycle of Fission Yeast
The fission yeast, *Schizosaccharomyces pombe*, basically grows in the haploid state. When the medium is deprived of nitrogen, the h^+ and h^- cells mate, undergo meiosis and sporulation.

Telomerase
Telomerase is a reverse transcriptase containing the RNA template for telomeric repeats. It compensates for the reduction of telomere length caused by the end replication problem of linear DNA. Fission yeast telomerase is encoded by the *trt1*$^+$ gene.

Telomere Shortening in the Absence of Telomerase
In humans, although telomerase activity is relatively high in germ cells, it is significantly low in most somatic cells, resulting in the gradual reduction of telomere length. Fission yeast telomerase (Trt1) is active in both the mitotic cell cycle and the meiotic cell cycle, thereby maintaining telomere length. In the absence of Trt1, however, the telomere length is gradually decreased, leading to cell growth arrest.

The telomere is a specialized heterochromatin localized at the end of the linear chromosome, and is essential for the multiple aspects of genome integrity. Telomere functions are performed mostly by telomere-binding proteins. Although many of the telomere-binding proteins are conserved among species, some variations exist. Recent studies of the fission yeast telomere-binding proteins have revealed that the components of the fission yeast telomere are more similar to those of humans than to those of budding yeast, indicating that fission yeast is evolutionarily more closely related to humans than to budding yeast in terms of the telomere.

1
Telomere-specific Complex

1.1
Taz1

In budding yeast, the Rap1 (scRap1, repressor/activator protein1) protein binds to the telomeric repeats as well as to the mating-type silencer elements and the UAS (upstream activation sequence) of the genes for ribosomal proteins, translational components, and glycolytic enzymes. scRap1 regulates telomere length and telomere position effect by recruiting two groups of proteins (see below). Thus, scRap1 is the most fundamental protein that performs telomere functions.

The fission yeast has three chromosomes, and each chromosome end has approximately 300 bp of telomeric repeats.

Cooper and coworkers attempted to identify a protein that directly binds to the telomeric repeats in fission yeast by a one-hybrid screen. The Taz1 protein was identified as a protein that specifically binds to the fission yeast telomeric repeats. The amino acid sequence of Taz1 is highly homologous with that of hTRF1 and hTRF2 in humans, and these proteins constitute the TTAGGG repeat factor (TRF) family (see Fig. 1). There is, however, no TRF homolog in budding yeast. They contain a TRFH (TRF homology) domain and a single Myb domain in common. Their carboxyl terminal Myb domains form the helix-turn-helix structure. hTRF1 and hTRF2 also directly bind to the human telomeric repeat DNA. It has been shown that the TRF family proteins form a homodimer via their TRFH domains to bind to the duplex telomeric repeats by means of their Myb domains, because a single Myb domain is not sufficient for association with DNA.

The localization of Taz1 is not limited to the telomeric repeats alone; Taz1 is also localized at the subtelomeric TAS (telomere-associated sequence) spanning approximately 10 kb adjacent to the telomeric repeats. Furthermore, Taz1 can be newly recruited to the TAS in the absence of the telomeric repeats, indicating that Taz1 recognizes not only the telomeric repeats, but also some elements (the DNA sequence or the associating proteins) in the TAS. In budding yeast, scRap1 is also localized at the subtelomeric region, suggesting that there is a common mechanism that induces the spreading of telomeric repeat-binding proteins into the subtelomeric region.

The disruption of the *taz1*$^+$ gene causes severe defects in telomere functions. First, telomeres are markedly elongated to ~2.5 to 4.5 kb in the *taz1* mutant. Taz1 is surmised to act as a negative regulator of telomerase, limiting the accessibility of telomerase to telomere DNA. Second, telomere silencing is alleviated in the *taz1* mutant. Genes that are transcriptionally active at the original locus are silenced when they are located near the telomeric repeats. This telomere silencing is caused by the specific chromatin structure. The deletion of *taz1*$^+$ probably results in a dramatic change of the higher-order chromatin structure at the telomeric repeats. Third, the deletion of *taz1*$^+$ causes a defect in telomere clustering toward the spindle pole body (SPB) in meiotic prophase. In vegetative cells, all the centromeres associate near the SPB, whereas telomeres cluster partially at the nuclear periphery apart from the SPB and the centromeres.

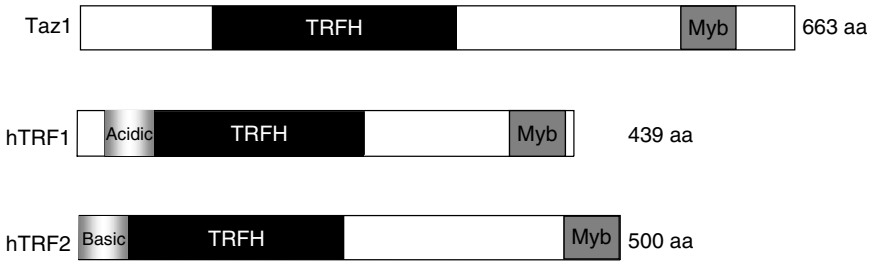

Fig. 1 Taz1 belongs to the TRF family. ''TRFH'' indicates a TRF homology domain, which mediates formation of a homodimer. ''Myb'' indicates a DNA-binding domain. Amino-terminal region of hTRF1 is very acidic, whereas that of hTRF2 is very basic. Amino-terminal region of Taz1 does not have either of the features.

Upon the induction of mating by nitrogen starvation, all the telomeres cluster toward the SPB, and the centromeres are displaced from the SPB. Then, the chromosomes (nucleus) move extensively in the cell with the SPB as the leading edge. In this horsetail stage, homologous chromosomes are aligned, inducing efficient homologous recombination. Thus, Taz1 is required for the stable association of the telomeres with the SPB during meiotic prophase and for the efficient meiotic recombination. Furthermore, *taz1* mutant cells produce abnormal spores, indicating that the precise telomere-SPB association is required for the completion of meiosis. Fourth, the *taz1* mutant exhibits lethal telomere fusions in the G1 phase after nitrogen starvation. This telomere fusion does not occur in the absence of pKu70 or Lig4, which mediates Ku-dependent nonhomologous end joining (NHEJ). Therefore, Taz1 protects chromosome ends from the DNA repair mediated by the Ku-dependent NHEJ. Fifth, the *taz1* mutant is defective in growth at 20 °C, although it grows normally at higher temperatures. At 20 °C, the *taz1* mutant shows DNA double-strand breaks (DSBs), G2/M cell cycle delay caused by DNA damage checkpoint, and chromosome missegregation. In addition, the mutant is hypersensitive to treatments that induce DSBs. Thus, Taz1 is required for preventing DSBs and for DNA repair throughout the genome.

1.2 Rap1 and Rif1

It is thought that scRap1 binds to the DNA as a monomer because scRap1 apparently has two Myb domains that are sufficient for the DNA-binding activity. The deletion of scRap1 is lethal, whereas some *rap1* mutants are viable. The *rap1-17* mutant has a strikingly elongated telomere DNA, suggesting that scRap1 is a negative regulator of telomerase, similar to the fission yeast Taz1. scRap1 recruits the two groups of proteins to the telomeres by interacting with its carboxyl terminal (RCT: Rap1 C terminus) domain. The proteins of the first group are scRif1 (Rap1-interacting factor1) and scRif2, which are mainly involved in telomere length control. The deletion of either protein causes moderate elongation of the telomere DNA, and the deletion of both proteins results in dramatic telomere elongation, similar to the phenotype of the *rap1-17* mutant. Proteins of the second group include Sir3 (silent information regulator 3) and Sir4, which are mainly involved in the formation of heterochromatin. Sir3 and Sir4 form a complex with Sir2, a histone deacetylase, and spread into the neighboring subtelomeric region from the telomeric repeats, resulting in a higher-order heterochromatin structure.

Fission yeast Rap1 (spRap1) was identified by a BLAST search in the genome database and by screening for nuclear proteins from the GFP-fusion genomic DNA library. spRap1, scRap1, and human Rap1 (hRap1) share homology in the BRCT (BRCA1 or breast cancer gene 1 C-terminal) domain and the Myb domain (see Fig. 2). spRap1 has an additional Myb-like domain that is similar to the second Myb domain of scRap1, although its physiological significance is not known. In contrast to spRap1, scRap1 and hRap1 have an RCT domain at their carboxyl termini. This suggests that protein–protein interaction is mediated in a different manner in fission yeast. Fission yeast Rif1 (spRif1) was identified as a homolog of scRif1 in the genome database. The amino acid sequence of spRif1 is homologous with that of scRif1 throughout the entire sequence.

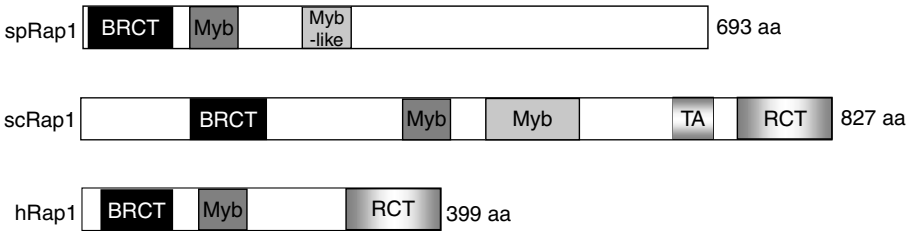

Fig. 2 Structures of the Rap1 family proteins. ''BRCT'' indicates BRCA1 C terminus. ''Myb'' indicates an Myb-related helix-turn-helix motif. ''RCT'' indicates Rap1 C terminus, which mediates interaction with the scRif proteins and with the Sir proteins in budding yeast. ''TA'' indicates a transactivation domain.

However, it is not known whether there is a Rif2 homolog in fission yeast.

Taz1 does not require spRap1 or spRif1 for telomere binding. On the other hand, both spRap1 and spRif1 interact with Taz1 and are localized at the telomeres in a Taz1-dependent manner. Thus, different from the case of scRap1, fission yeast Rap1 does not directly bind to the telomere DNA at least in mitotically growing cells. hRap1 also does not bind directly to the telomere DNA, and is localized at the telomeres via interaction with TRF2. It is speculated that the structure of the Rap1 protein was changed during the course of evolution. One possibility is that budding yeast scRap1 has gained two Myb domains for direct binding to the telomere DNA as a monomer. The second possibility is that fission yeast and human Rap1 proteins have lost one Myb domain and gained TRF proteins instead.

Both spRap1 and spRif1 are involved in telomere length control (see Fig. 3). The deletion of spRap1 causes a marked elongation of the telomere DNA to the extent similar to that of the *taz1* mutant. The *rif1* mutant has telomere DNA that is approximately 200 bp longer than that of the wild type. The *taz1rap1* and *taz1rif1* mutants have telomere lengths similar to that of the *taz1* mutant, indicating that spRap1 and spRif1 regulate telomere length in a Taz1-dependent manner, which is consistent with the fact that spRap1 and spRif1 are recruited to the telomeres by interacting with Taz1. The *rap1* mutant has additional telomere phenotypes. First, telomere silencing is strikingly alleviated. Second, it is defective in telomere clustering toward the SPB in meiotic prophase, resulting in the production of abnormal spores (see Fig. 4). Collectively, three telomere functions, namely, telomere length control, telomere silencing, and telomere clustering toward the SPB in the meiotic prophase, are impaired in the *rap1* mutant cells, in which Taz1 is still localized at the telomeres. Therefore, Taz1 itself cannot fulfill those telomere functions, and its primary role is to recruit such telomere regulators as spRap1 and spRif1 to the telomeres. However, not only does Taz1 recruit spRap1 and spRif1, but it is also required for the stability of the whole genome, whereas spRap1 and spRif1 are not. There may also be other regulators that associate with Taz1.

Indirect immunofluorescence microscopy has shown that spRap1 is sometimes colocalized with the telomeres and the SPB in the *taz1* mutant at the horsetail stage. This suggests two possibilities. The first is that spRap1 has an intrinsic tendency to be localized near the SPB.

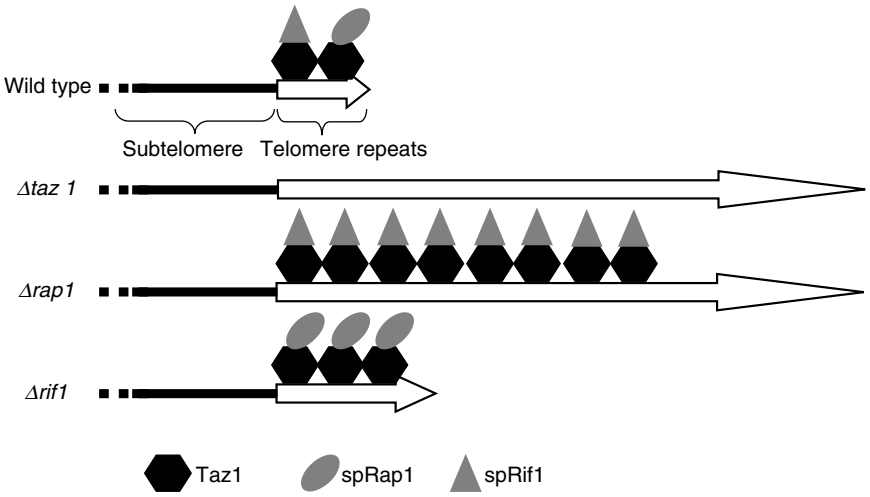

Fig. 3 Telomere-binding proteins regulate telomere length. In the wild-type strain, both spRap1 and spRif1 are associated with Taz1 at the telomeres. In the *taz1* mutant, none of them are localized at the markedly elongated telomeres (exception: spRap1 in meiotic prophase). In the *rap1* mutant, Taz1 and spRif1 are localized at the telomeres, but telomere DNA is markedly elongated. In the *rif1* mutant, Taz1 and spRap1 are localized at the telomeres, and telomere DNA is moderately elongated.

The protein complex that specifically functions for telomere clustering toward the SPB may recruit spRap1 to the SPB in a Taz1-independent manner. The second possibility is that spRap1 has an activity to bind to telomere DNA inefficiently. In fact, spRap1 contains an additional Myb-like domain besides a Myb domain that is conserved in yeasts and humans (described above). These two Myb domains, although incomplete, may serve as DNA-binding domains for spRap1 in the meiotic prophase. Localization of spRif1 is different from that of Taz1 and spRap1. spRif1 is localized at the telomeres, although mainly in the nucleolus in the wild-type cells. This suggests that spRif1 has functions that are not related to the telomere maintenance.

hRap1 is also involved in telomere length control. The overexpression of hRap1 results in telomere elongation. On the other hand, the primary function of hRif1 seems to be different from those of spRif1 and scRif1. hRif1 is localized at the DSBs, not at the functional telomeres. hRif1 is regulated by ataxia telangiectasia-mutated (ATM) and 53BP1 and functions in the S-phase checkpoint pathway. It is possible that the yeast Rif1 proteins also have similar functions.

1.3 End-binding Proteins

The Ku complex functions as a heterodimer consisting of Ku70 and Ku80, and basically binds to the DSBs to mediate DNA repair by NHEJ. Fission yeast Ku70 (pKu70) and Ku80 (pKu80) were identified by a BLAST search. pKu is localized near the chromosome ends in a Taz1-independent manner. The deletion of pKu70/pKu80 results in stable but shorter telomeric repeats, elongation of G-rich overhang, and TAS rearrangement. The rearrangement of TAS in the *pku* mutant

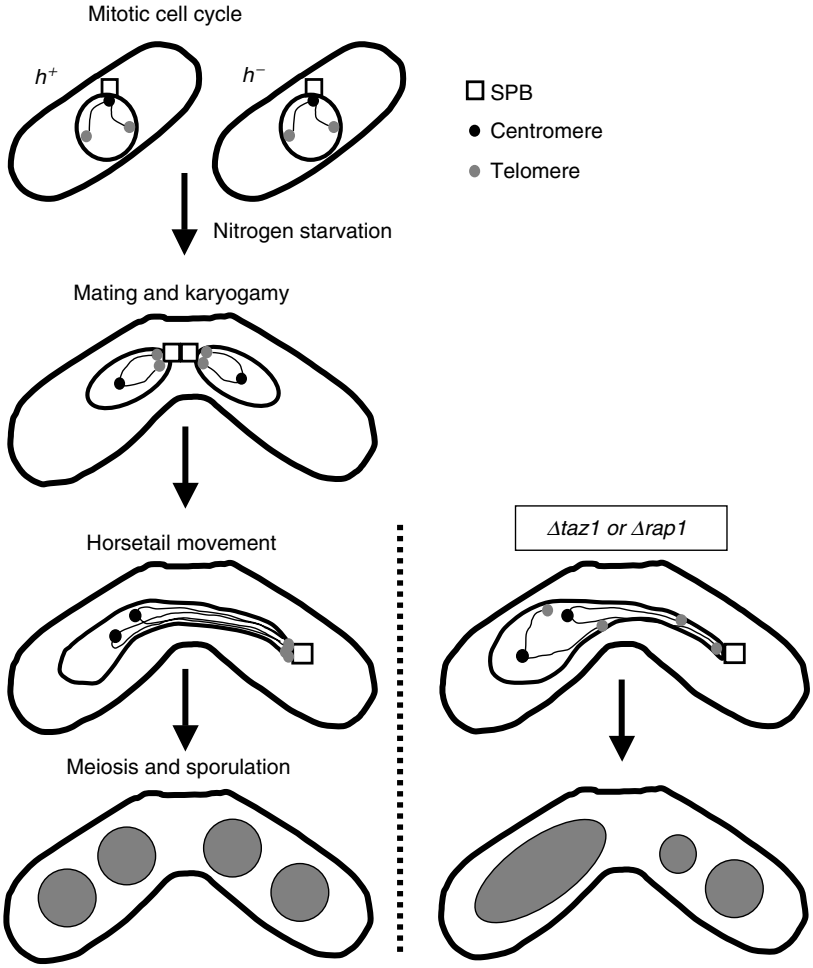

Fig. 4 The Taz1–spRap1 complex is required for normal meiosis. In vegetative cells, all the centromeres cluster near the SPB, whereas the telomeres cluster partially near the nuclear periphery (a single chromosome is shown in this figure). Upon nitrogen starvation, the h^+ and h^- cells mate and start karyogamy. At the same time, the telomeres cluster toward the SPB, whereas the centromeres are displaced from the SPB. After karyogamy, the nucleus moves extensively in the cell with the SPB as the leading edge (the horsetail movement). After meiosis is completed, four spores (shown as the gray circles) are produced in a zygote. In the *taz1* or *rap1* mutant, telomere clustering at the meiotic prophase is defective, and spores of abnormal number and size are produced.

is Rhp51 (fission yeast Rad51 homolog)-dependent, and Rhp51 is localized at the telomere especially in the absence of pKu, indicating that pKu sequesters Rhp51 from the telomere ends to inhibit homologous recombination. Furthermore, pKu protects the telomere end, and the lack of pKu leads to the acceleration of senescence in the absence of telomerase. Although the primary function of the pKu is to

mediate NHEJ, pKu at the telomeres is regulated not to fuse chromosome ends. Taz1 directly or indirectly prevents pKu from treating the telomeres as DSBs. In budding yeast, yKu70/yKu80 is involved in the telomere silencing and in the telomere localization to the nuclear periphery, as well as in the telomere length control. However, pKu is not involved in the telomere silencing, indicating that pKu and yKu function in differently at the telomeres.

Fission yeast Pot1 protein was identified by a BLAST search for a protein containing limited homology to the α-subunits of ciliate telomere proteins. The Pot1 protein specifically binds to the telomeric G-rich single-strand DNA. The *pot1* mutant loses the telomere DNA very quickly after germination, and most of the cells become elongated after ~10 generations. Most of the elongated cells show chromosome missegregation (see Fig. 5). However, some survivors emerge after ~75 generations, and all the three chromosomes are circularized in most of those cells. Thus, Pot1 directly protects the telomere at the end. Human Pot1 also specifically binds to the telomeric G-rich single-strand DNA, indicating that the function of Pot1 is conserved in fission yeast and humans. On the other hand, there is no apparent ortholog in budding yeast. However, the budding yeast Cdc13 protein binds to the telomeric G-rich single-strand DNA and regulates the accessibility of telomerase to the telomeres via interaction with the Est1 (ever shorter telomeres1) protein, which is associated with telomerase. In humans, hPot1 is recruited to the telomeres by interacting with PTOP/PIP1, which interacts with the TIN2-TRF1 complex at the telomeres. Thus, it is speculated that

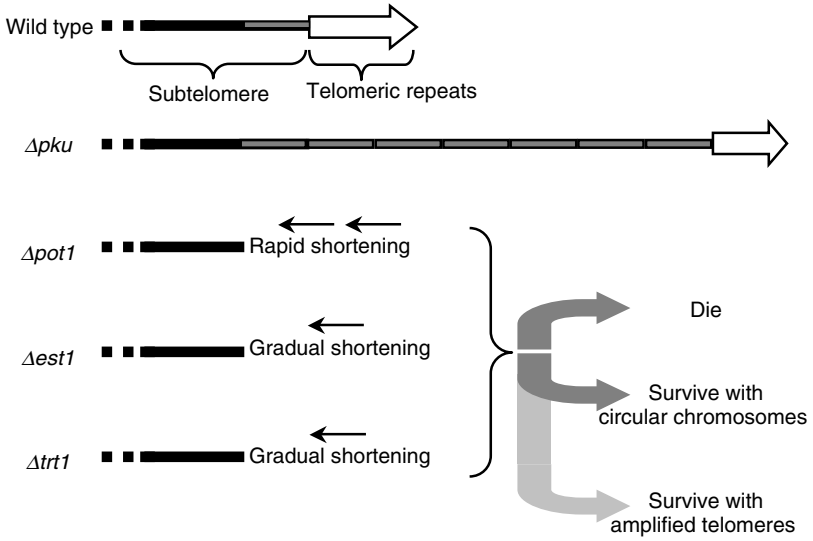

Fig. 5 Telomere length regulation by the telomere end–binding proteins. In the *pku* mutant, length of the telomeric repeats is slightly reduced, but telomere-proximal region of the TAS is amplified (gray boxes). In the *pot1*, *est1*, and *trt1* mutants, telomeres are shortened until cells die or survivors with circular chromosomes emerge. A very small population of the survivors has chromosomes with amplified telomere DNA.

the localization of hPot1 at the G-rich overhang is regulated by TRF1, which controls the accessibility of telomerase and the telomere length. The regulatory mechanism of fission yeast Pot1 is not known.

In budding yeast, scEst1 recruits or activates telomerase at the end of telomeres. In fission yeast, spEst1 was identified by a BLAST search as a protein that contains significant homology only at a small region near its amino terminus. Similar to scEst1, spEst1 physically interacts with telomerase, although it is not required for the catalytic activity of telomerase. The phenotype of the *spest1* mutant is very similar to that of the *trt1* mutant, that is, the telomere DNA is gradually shortened after germination (slower than the *pot1* mutant), and some survivors with circular chromosomes emerge. Thus, spEst1 may be required for the recruitment of telomerase to the telomere ends. Budding yeast Cdc13 associates with scEst1, so fission yeast Pot1 may interact with spEst1 to recruit telomerase.

2 Telomere Heterochromatin

2.1 Gene Silencing

Telomeres are specialized heterochromatin. Telomere silencing is alleviated in the mutants of many proteins. The first group contains Taz1 and spRap1, which are telomere-specific proteins. The second group contains Swi6, Clr4, and Rik1, which are required for heterochromatin formation at all the heterochromatin loci. Swi6 is the homolog of HP1s (heterochromatin protein1) in humans and fly. Clr4 is a methyltransferase specific for Lys9 of histone H3. The methylation of histone H3 at Lys9 is required for the binding of Swi6 to the histones. Rik1 interacts with Clr4 to act in concert to methylate histone H3 at Lys9 at the heterochromatin loci. Mutations in these *swi6*, *clr4*, and *rik1* genes do not cause any defects in telomere length.

2.2 Swi6

Indirect immunofluorescence microscopy and chromatin immunoprecipitation (ChIP) analyses have shown that Swi6 is localized at the heterochromatin loci, such as the centromeres, the telomeres, and the silent mating-type locus. Swi6 recruits cohesin molecules to the heterochromatin regions. Enriched cohesins at the pericentric region of the centromere are required for the precise chromosome segregation at mitosis. In fact, the *swi6* mutant shows the lagging chromosomes at a high frequency. At the silent mating-type locus, Swi6 is localized at the K-region, a ~15 kb chromosomal domain including the *mat2* and *mat3* loci. Swi6 heterochromatin is required for the maintenance of the silent epigenetic state of the K-region. Collectively, it seems that Swi6 has local functions at the heterochromatin regions. However, the function of Swi6 at the telomeres is not known. In budding yeast, Sir3, a component of the silencing complex, is localized at the telomeres and represses the expression of the stress-responsive genes of the *PAU* family located at the subtelomeres. When cells are in a stress condition, the Sir3 proteins are hyper-phosphorylated by the Mpk1 kinase and are removed from the telomeres, resulting in the derepression of the *PAU* family genes. No such stress-responsive genes at the fission yeast subtelomeres have been reported so far. However, there is an open reading frame

(ORF) of a putative RecQ helicase homolog at least on the four chromosome ends (Chr. I and II). The expression of the ORF is induced when the telomere DNA is shortened by the deletion of telomerase. The overexpression of the RecQ helicase homolog in the telomerase-deficient cells results in the earlier recovery from the senescence. Although the overexpression of the RecQ helicase homolog itself is apparently not toxic to the cells, Swi6 at the telomeres may be required for the repression of the RecQ helicase homolog.

2.3 RNAi and RITS

The pericentric outer (*otr*) region of the centromere consists of two types of repeat sequences, the *dg* and *dh* repeats. There exists a DNA sequence called *cenH* (centromere-homologous repeat) in the K-region at the silent mating-type locus. The *cenH* DNA sequence is highly homologous with those of the partial *dg* and *dh* repeats. Interestingly, the components of the fission yeast RNAi machinery, such as Argonaut (Ago1), Dicer (Dcr1), and RNA-dependent RNA polymerase (Rdp1), are involved in the establishment of Swi6 heterochromatin at the centromeres and at the silent mating-type locus. siRNAs are produced by Rdp1 and Dcr1 using the *dg* and/or *dh* repeats as a template, and then an RNAi effector complex RNAi-induced initiation of transcriptional gene silencing (RITS) containing Chp1, Tas3 and Ago1, which is associated with the

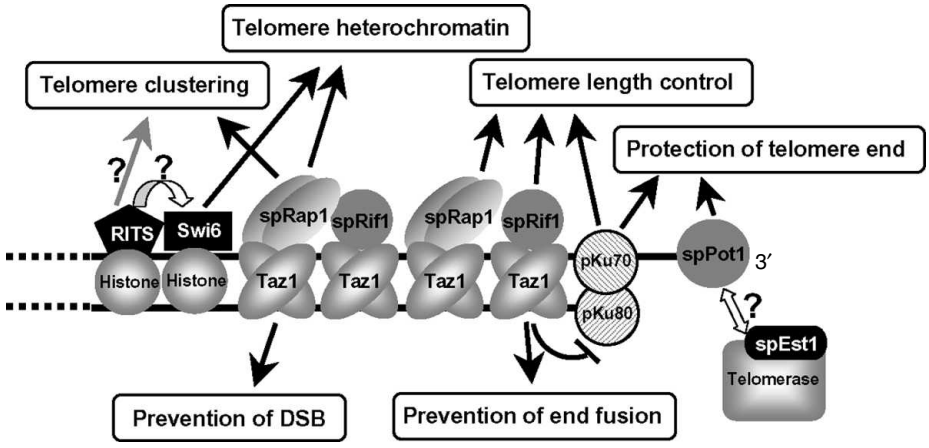

Fig. 6 Telomere-binding proteins in fission yeast. spRap1 and spRif1 are recruited to the telomeres by interacting with Taz1. spRap1 is involved in telomere length control, maintenance of the telomere heterochromatin and telomere clustering toward the SPB in meiotic prophase. spRif1 is involved in telomere length control. Taz1 prevents the Ku-dependent chromosome end fusion and DSBs throughout the genome. On the other hand, the pKu70/pKu80 heterodimer is involved in telomere length control and in the stability of TASs. Pot1 associates with the G-rich overhang and protects chromosome ends. Pot1 regulates the accessibility of telomerase possibly by recruiting spEst1 that associates with telomerase to the telomere ends. Swi6 (a HP1 homolog) and the RITS complex are localized at the telomeres in a methylation of histone H3 at Lys9-dependent manner. The RITS complex is possibly involved in the establishment of Swi6 heterochromatin at the telomeres and may be required for the telomere clustering.

siRNA, is recruited to the original target DNA sequence. It is thought that Clr4 is also recruited to the target sequence with the RITS complex to methylate histone H3, and then Swi6 is recruited to the methylated histone H3. Similar to Swi6, the RITS complex is also stably localized at the heterochromatin loci including the telomeres in a Clr4-dependent manner. Although how the RITS is recruited to the telomeres remains unknown, it is possibly recruited to the telomeres via the RNAi pathway. The RNAi mutant shows a defect in the telomere clustering both in the mitotic cell cycle and at the meiotic prophase, resulting in abnormal meiosis. Furthermore, the *clr4* and *rik1* mutant, in which the RITS complex is not localized at the heterochromatin loci, also show the defect in telomere clustering at the meiotic prophase. Therefore, some components of the RITS complex may be required for sticking the telomeres together and the telomere dynamics in the nucleus (see Fig. 6).

Keywords

Abaxial
Dorsal, that is, facing away from the axis of an organ or organism; the lower side of a leaf is termed *abaxial*.

Accession
Plant genotype of a species collected at a specific location.

Acetylation
Introduction of an acetyl group (CH_3CO) into a compound.

Adaxial
Ventral, that is, nearest to or facing toward the axis of an organ or organism; the upper side of a leaf is termed *adaxial*.

ADP-ribosylation
Transfer of adenosine diphosphate ribose to proteins.

Angiosperms
Plants having seeds in a closed ovary.

Apomict
A plant that reproduces asexually through seed.

Bacterial Artificial Chromosomes (BACs)
A DNA-cloning vector capable of incorporating fragments of 100 to 300 kb (average of 150 kb) in *Escherichia coli* cells.

Centromere
The region of a chromosome required for chromosome segregation, usually repetitive sequences, to which the spindle attaches during mitosis and meiosis.

Cleaved Amplified Polymorphic Sequences (CAPS)
Sequences that show polymorphism between individuals when a particular locus is amplified, and the product digested with restriction enzymes, resulting in different sized restriction fragments.

Colinearity
Conservation of gene order in chromosomes over distantly related species.

Dicots
Short for dicotyledonae-an angiosperm with two embryonic leaves (cotyledons).

Dioecious Plants
Having male and female reproductive organs on separate plants.

Diploid
Containing paired chromosomes (2 $\times$ the haploid number).

DNA Polymorphism
A difference in the DNA sequence at a particular locus between individuals.

Ectopic Expression
Overexpression or expression in addition to endogenous gene expression.

Epigenetics
The study of heritable changes in gene expression that occur without a change in DNA sequence.

Euchromatin
Uncondensed, transcriptionally active chromatin.

Exon
Protein coding part of a gene.

Expressed Sequenced Tags
A sequence, derived from a cDNA library, that has been expressed at some stage of development, and that is used to identify the gene locus.

Forward Genetics
A classical genetic approach, where a gene is defined by a mutant phenotype.

Gametophyte
The gamete-producing organism or phase in the life cycle of a plant: the megagametophyte is the female gametophyte (embryo sac), containing the female gametes (egg and central cell); the microgametophyte is the male gametophyte (pollen), containing two sperm cells.

Genetic Map
The linear positioning of genetic markers (providing a visible phenotype) within a chromosome, or genome, as determined by their recombination frequency.

Haploid
Containing one set of unpaired chromosomes.

Hermaphroditic Plants
Having both male and female reproductive organs in the same flower.

Heterochromatin
Condensed, transcriptionally inactive, chromatin.

Hexaploid
Containing six sets of paired chromosomes.

Histone
Main protein of chromatin.

Homeotic Genes
A class of genes that when mutated lead to homeotic transformations. Homeotic genes play a central role in animals and plants in pattern formation and the specification of organ identity.

Intron
Nonprotein coding part of a gene.

Linkage Groups
Genes that tend to be transmitted together.

Locus
The position of a gene on the chromosome.

Methylation
Addition of a methyl group (CH_3) to a substrate.

Monocots
Short for monocotyledonae-an angiosperm with one embryonic leaf (cotyledon).

Monoecious Plants
Having separate male and female flowers on the same plant.

Morphological
Concerned with the visible structure of an organism.

Nucleosome
A unit made up of a histone (H) protein complex, wrapped in two turns of DNA.

Orthologous Genes
Genes that have diverged after a speciation event.

ParalogousGenes
Genes that have diverged after a duplication event.

Pericentromeric
Pertaining to the region of repetitive DNA at the periphery of the centromere.

Phosphorylation
The addition of a phosphate (PO_4) group to a protein.

Phylogenetic Relationship
The relationship of species or a taxonomic group of organisms, as derived from the comparison of characteristics such as DNA sequence or other characters.

Physical Map
The linear positioning of physical markers, or identifiable landmarks on DNA, such as restriction enzyme cleavage sites within a chromosome or genome, as determined by their recombination frequency. (The highest resolution physical map is the nucleotide sequence of the genome.)

Polyploid
A nucleus having more than one set of paired chromosomes.

Rapid Amplified Polymorphic DNA
Variation in the size of DNA fragments that arise from the amplification of DNA, from different individuals, using short nucleotide primers. This variation arises from DNA sequence polymorphisms that affect the efficiency with which the primer binds to the DNA sites.

Recombination
Combining genes or characters from parents so that the progeny contains a combination that is not the same as in either parent.

Retroelements
Genetic elements that transpose replicatively, leaving a copy of itself at the launch site and reinserting a new copy in the genome.

Reverse Genetics
A strategy that is used to identify the function of a gene, the sequence of which has been identified, by screening for mutations in that gene (using gene targeting, or the recovery of EMS, or insertional mutants).

Satellite Repeat
Highly repetitive eukaryotic DNA, often located around centromeres.

Simple Sequence Length Polymorphisms (SSLP)
Simple nucleotide repeat sequences that are highly variable in length between individuals.

Sumoylation
A protein modification, biochemically analogous to, but functionally distinct from, ubiquitination. Sumoylation involves the covalent attachment of a SUMO (small ubiquitin-related modifier) to substrate proteins.

Synteny
Colinearity between species of wide evolutionary distance.

Telomeres
Highly repetitive DNA, capped by specific proteins, that protect the ends of chromosomes.

Tiling Path
A minimum set of overlapping clones, usually BACs or YACs containing genomic DNA that make a contiguous sequence of genomic DNA that is anchored to the combined physical and genetic map.

Transformation
A permanent heritable modification of a cell by the uptake and incorporation of exogenous DNA.

Transposons
Sequences of DNA that can move, or transpose, around the genome.

Ubiquitination
The modification of a protein by addition of a ubiquitin molecule to lysine residues that targets the protein for destruction. Ubiquitination of histones leads to a conformational change in chromatin structure.

Vernalization
Prolonged cold treatment of plants that induces flowering.

Yeast Artificial Chromosomes (YACs)
A DNA cloning vector based on a bacterial plasmid that contains a yeast centromeric region (CEN), a yeast origin of replication (ARS), and a telomere region at the end of each arm. YACs are capable of containing more than 1 megabases of cloned DNA.

The genome of the Thale Cress, *Arabidopsis thaliana*, was the first plant genome to be fully sequenced, providing a tool for the rapid characterization of biological processes. This versatile model organism has had a major impact on our understanding of the physiology, growth, and development of flowering plants, and their response to environmental stress. An in-depth understanding of model organisms, coupled with knowledge of crop systems, will provide rapid advancements in technology, including genetic engineering, that are required to overcome future predicted global climate changes and short falls in food production.

1 Introduction

The importance and impact of plants on our planet is irrefutable, they are essential for its well-being. Our planet's biomass is mostly made up of plants, a characteristic illustrated by images of earth from space.

Plants are highly adaptive organisms, surviving in diverse and often severe environments, from deserts to marshlands. They combat disease and predation. They adjust their behavior to seasonal and diurnal changes, moving to avoid shade, or in anticipation of the rising sun. Some can even count; the Venus flytrap ignores a single stimulus, but snaps shut in response to a second one. Plants have evolved a wide variety of reproductive strategies. They reproduce sexually as hermaphroditic, monoecious, or dioecious species, or asexually by apomixis or through tubers or stolons. They include some of the largest and oldest living organisms on the planet. These features alone provide compelling reasons for plant study; however, coupled with our dependence on these organisms for food, medicines, clothing, and building materials, a deeper understanding of how these organisms function is essential to our future well-being.

The wide variety of exploited plant products has largely been dependent on the existence of a large reservoir of diverse plant species. This diversity has, in many ways, hampered progress in the functional analysis of plants, since many plant species of economic importance are also diverse. In animals, it has long been accepted that model organisms would provide acceptable alternatives to human experimentation. In plants, however, no widely accepted model plant species received early adoption. Historically, owing to plant diversity, it was felt that no single plant organism could provide universally applicable information of use to other plant species. This led to a preference for studies in economically important and frequently diverse plant species, which resulted in slow progress. Major drawbacks of many of the economically important crop species, which have made genetic and molecular studies difficult, are the large size and highly repetitive nature of their polyploid genomes. Bread wheat, for example, is a hexaploid with a genome of 1.6×10^{10} bp, 80% of which consists of repetitive DNA sequences. Although repetitive DNA is also a feature of animal genomes, including the human genome, polyploidy is rarely seen in animals; it was thought to occur only in a few insects, amphibians, and reptiles until 1999, when it was discovered in one mammal; a desert rodent in Argentina.

1.1
Model Organisms

Model diploid organisms in animal studies revealed that, despite the divergence of invertebrates and vertebrates more than 600 million years ago, many genes, including the *HOX* homeotic gene family, are functionally interchangeable between diverse organisms, for example, flies and vertebrates. This has allowed remarkable parallels to be drawn between the fruit fly model and human genetics. Since angiosperms are thought to have evolved from a common ancestor within the last 150 million years, genes identified in a model angiosperm could be expected, with confidence, to functionally replace an orthologous gene in many of the 250 000 angiosperm species.

In 1943, before these discoveries, Friedrich Laibach, realizing the benefit of adopting a model plant species, suggested the Thale Cress, *Arabidopsis thaliana*, as a model plant system (Fig. 1). He recognized that *Arabidopsis* had many features that would make it an ideal model organism for plant studies. It has a short life cycle, of between 6 to 8 weeks, it is physically small (20–30 cm tall at maturity), it can be self-fertilized and outcrossed, producing large quantities of seed (up to 6000 seeds per plant), and it is a genetically tractable diploid. Despite these many

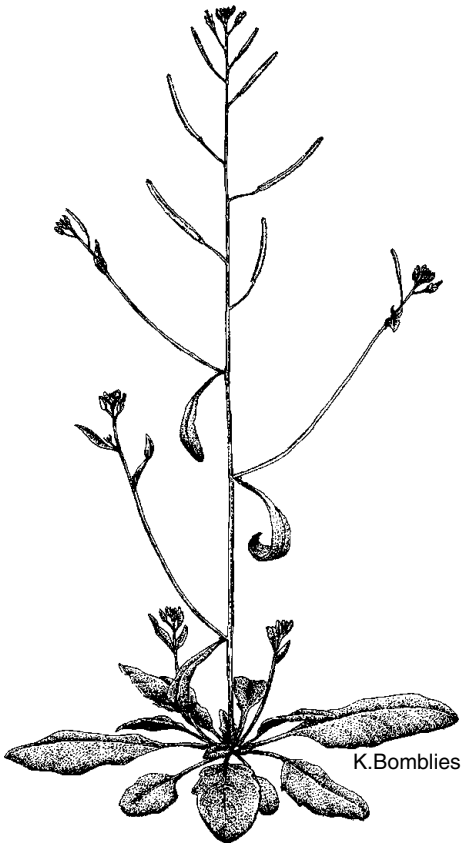

Fig. 1 A drawing of a mature flowering wild-type *Arabidopsis thaliana* plant (courtesy of Kirsten Bomblies, University of Wisconsin, Madison).

advantages for classical genetic studies, it was not until the 1960s that enthusiasm for *Arabidopsis* really developed. In addition to these earlier identified features, it was soon discovered that *Arabidopsis* could be mutated easily, and contained a small number of chromosomes (a haploid number of five chromosomes), as revealed by microscopic observations, and later by linkage analysis. In fact, it is this low number of chromosomes that has allowed the efficient identification of linkage groups in *Arabidopsis*.

2 Genome Structure

When confronted with an uncharacterized genome, isolates or accessions with different morphological traits can be used in classical genetic studies to determine the physical relationship (linkage) of the genes responsible for these traits.

2.1 Linkage Groups

Linkage analysis is dependent on recombination between different loci. These different loci (morphological or classical markers) are generated most easily by mutagenesis, and their position with respect to one another in the genome can be identified by their frequency of recombination. This type of analysis led to the production of an extensive genetic map. The interest in *Arabidopsis* as a model organism really accelerated when, in the early 1980s, the small size and simple structure of the genome was determined and high-efficiency transformation protocols were established.

Together with classical morphological markers, linkage analysis was performed with molecular markers, taking advantage of another important feature of *Arabidopsis*: the high degree of polymorphism at the DNA level between accessions. Restriction fragment length polymorphisms (RFLPs) and later, to a lesser extent, PCR-based markers, such as rapid amplified polymorphic DNAs (RAPDs), have been used to construct linkage maps in *Arabidopsis*. This type of analysis led to the production of a physical map, which was later integrated with the genetic map. These markers, together with the development of more reliable PCR-based markers, CAPS (cleaved amplified polymorphic sequences) and SSLP (simple sequence length polymorphisms), were used to construct a high-resolution combined physical and genetic map. The small size of the genome and this extensive map made *Arabidopsis* an attractive proposition for whole genome sequencing. The sequencing program began with a collaborative international initiative in 1996. To facilitate this sequencing effort, a minimal tiling path of large-insert yeast artificial chromosomes (YACs) and bacterial artificial chromosomes (BACs) was assembled, spanning the entire genome. These BAC and YAC contigs, anchored to the combined physical and genetic map, provided a framework that allowed the *Arabidopsis* genome to be sequenced. As a consequence of this enormous international effort, the *Arabidopsis* genome was the first reference plant genome to be sequenced.

2.2 Genome Sequence

The original analysis of the sequence revealed 25 498 genes in about 125 Mb of DNA (a figure, which is slowly increasing as methods of gene prediction improve, currently $>28\,000$). In *Arabidopsis*, the

average gene length is around 2000 bp with an average exon length of 250 bp (~5 per gene) and an average intron of 180 bp in length. This means that *Arabidopsis* genes are mainly exonic. The rice genome is larger, containing 430 Mb of DNA packaged into 12 chromosomes. The rice genome sequence analysis has revealed a total of approximately 50 000 genes. These genes are similar in length to *Arabidopsis* genes at around 2350 bp, with an average exon length of 260 bp (~4 per gene) and an average intron length of 330 bp. Here, the genes are nearly equally exonic and intronic. This is in stark contrast to the human genome, which has a similar number of genes as found in *Arabidopsis* (Celera suggests 26 383 genes), but, here, the genes are mainly intronic and are contained in some 3000 Mb of DNA. (The average length of a human gene is 27 000 bp [ranging between 20 – 50 kb], the average exon length is 236 bp [~5 per gene], and the average intron is 5500 bp.)

2.3 Chromsome Organization

The *Arabidopsis* genome sequence provides information on chromosomal organization, including telomeres, centromeres, and nucleolar organizers that maintain genome stability even during evolutionary changes in genome structure.

2.3.1 Telomeres

Arabidopsis chromosomes, like all eukaryotic chromosomes, are capped by complex nucleoprotein structures known as *telomeres*, which stabilize the genome (Fig. 2b). The length of telomeres varies among eukaryotes, for example, in tobacco, telomeres are 150 kb, while in humans, telomeres are less than 20 kb. *Arabidopsis* telomeres were the first higher eukaryote telomeric DNA sequences to be determined. They are composed of TTTAGGG repeats, averaging 2 to 3 kb in length with G-overhangs of 20 to 30 nucleotides. Telomeric DNA is usually maintained by telomerase enzymes. Mutations in telomerase cause telomere shortening and ultimately cell death. Telomerase-deficient *Arabidopsis* plants show a remarkable tolerance to genome stress, showing no visible abnormalities even after five generations of inbreeding. After further inbreeding, telomerase-deficient mutants, however, show end-to-end chromosome fusions, which result from uncapped chromosome ends being recognized as damaged DNA. Varying degrees of developmental abnormalities follow, ultimately resulting in lethality by the 10th generation. Other mutations in *Arabidopsis* also produce dysfunctional telomeres; however, the slow onset of lethality makes *Arabidopsis* an excellent model for telomere study. Interestingly, although telomeres play a role in genome stability, the *Arabidopsis* genome sequence has revealed an unexpected degree of large segmental duplications and rearrangements. More than 60% of this small genome consists of duplicated DNA, suggesting that plant genomes are in a constant state of flux.

2.3.2 Centromeres

One of the most important domains of eukaryotic chromosomal DNA is the centromere (Fig. 2b). The centromeric regions are required for normal chromosome segregation during meiosis and mitosis. They usually consist of highly repetitive DNA that mediates the attachment of the spindle to the chromosomes during cell division. Despite their common function, centromeric DNA sequences are not conserved between organisms. *Arabidopsis* centromeres contain repetitive DNA

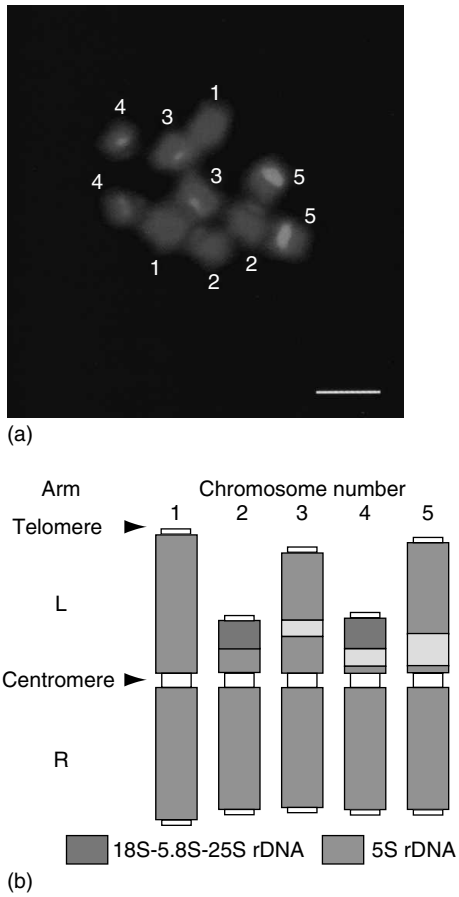

Fig. 2 (a) DAPI-stained metaphase chromosomes of *Arabidopsis thaliana* Landsberg *erecta*, showing green fluorescein signals from the 5S rDNA and red Cy-3 signals from the 18S-5.8S-25S rDNA. Chromosomes were identified by the FISH pattern and numbered according to the linkage group. Bar = 2 μm. (b) A karyotype showing the location of the 5S rDNA18S-5.8S-25S rDNA, centromeric 180 bp repeats and the telomeric repeats (Murata, M., Heslop-Harrison, J.S., Motoyoshi, F. (1997) Physical mapping of the 5S ribosomal RNA genes in *Arabidopsis thaliana* by multi-color fluorescence *in situ* hybridization with cosmid clones, *Plant J.* **12**, 31–37.) This figure is copyrighted by Blackwell Publishing and is reprinted with permission. (See color plate p. xxiv.)

elements, including telomere-like repeats, transposons, and retroelements; however, the most abundant sequence (several megabases) is a 180-bp satellite repeat, which forms long tandem arrays. The *Arabidopsis* genome contains five centromere domains, one for each chromosome. The sequence data corresponding to these regions are incomplete because of the inherent difficulties in sequencing large regions of repetitive DNA. It is apparent, however, that in *Arabidopsis*, as in maize and rice, the centromeric satellite repeat is a key functional element of centromere DNA. These satellite sequences associate with centromere-specific histone H3 variants (CenH3s). CenH3s are rapidly evolving proteins, suggesting that they respond to changes in rapidly evolving centromeric repeat sequences.

2.3.3 Nucleolar Organizers (NORs)

Like all organisms, *Arabidopsis* contains ribosomal DNA (rDNA), encoding clustered arrays of the 18S, 5.8S, and 25S ribosomal RNA (*rRNA*) genes, which, in concert with 5S RNA, form the structural core of cytoplasmic ribosomes (the sites of protein manufacture). These clusters of active *rRNA* genes are known as *nucleolar*

organizers (NORs) since, during interphase, the nucleolus forms at the site of rRNA transcription and ribosome assembly. In *Arabidopsis,* these NORs are roughly 3.6 to 3.7 Mbp, comprising 360 to 370 *rRNA* genes, and are situated adjacent to the telomeres on the short arm of chromosomes 2 and 4 (Fig. 2a and b). In contrast, the 5S *rRNA* genes are localized in clusters on chromosomes 3, 4, and 5, toward the centromeres (Fig. 2a and b). Coding regions of *rRNA* genes are highly conserved, which allows the phylogeny of diverse organisms to be established by comparative DNA sequence analysis. The intergenic spacer regions containing control elements, however, are more variable. The variants differ in the number of repetitive sequences located in the intergenic spacer region, suggesting that the *rRNA* genes evolve together as a group (concerted evolution). Comparing intergenic space sequences allows the phylogeny of very closely related species, or even isolates of the same species, to be established.

A powerful approach to look at the structure of chromosomes is to use fluorescence *in situ* hybridization (FISH) with chromosome-specific DNA probes. Using this chromosome painting technique, the physical position of the 5S ribosomal RNA genes, described earlier, was identified (Fig. 2a and b). Using a set of FISH probes, inter- and intrachromosomal rearrangements of mitotic or meiotic chromosomes could be determined, allowing the identification of break points that result in natural or mutagen-induced rearrangements. This approach has been used in large-scale physical mapping to compare homologous loci in *Arabidopsis* and *Brassica rapa* (Cabbage and Mustard), a close relative, providing evolutionary data on genome structure.

2.4 Synteny

One of the incentives for the genome sequencing initiative was an expectation of significant colinearity between *Arabidopsis* and more economically important genomes. The hope was that important genes, such as those encoding disease resistance, found in the model organism, would help locate similar genes in crops. Many studies have shown, however, that genome structure is constantly changing, causing differing degrees of complexity, limiting the usefulness of *Arabidopsis* as a reference organism for gene order. The ancestral lineages of *Arabidopsis* and *Brassica* diverged 12.2 to 19.2 million years ago and typically show more than 85% nucleotide conservation in coding regions. Despite these similarities, there is extensive divergence between the structures of these genomes, making it difficult to identify even the most closely related segments of the *Brassica oleracea* and *Arabidopsis thaliana* genomes. This is, in part, because of extensive amplifications and rearrangements in plant genomes. Despite these rearrangements, 34 significant regions of colinearity have been identified between *B. oleracea* and *A. thaliana,* which represent well over a quarter of the *B. oleracea* genome. Comparisons made between the sequence of the rice genome and *Arabidopsis* have revealed very low levels of colinearity. These lineages diverged approximately 200 million years ago. This low level of synteny suggests that further reference plants should be sequenced so that evolutionary intermediates can be analyzed. This, however, presents a dilemma. Should phylogenetically important species be sequenced, or should efforts be focused directly on economically important

species? Although synteny is limited between rice and *Arabidopsis*, comparisons between rice and other cereals show high degrees of synteny at the genetic map level. This has allowed the integration of their respective genetic maps, aiding fine mapping and candidate gene identification. Marker colinearity of rice and barley (*Hordeum vulgare*) chromosomes, for example, has provided a candidate gene for the *uzu* mutant that causes semidwarfism in barley. The position of *uzu* corresponds to a rice gene, *D61*, which is similar to the *Arabidopsis* brassinosteroid-insensitive1 (*BRI1*) gene (mutations in *BRI1* cause dwarfism in *Arabidopsis*). A comparison of the *HvBRI1* sequences in *uzu* and normal barley identified a single nucleotide substitution in the mutant gene, demonstrating the usefulness of this type of analysis. Comparative analysis can, however, be frustrated by the surprising number of rearrangements and deletions that have occurred at the microlevel between rice and closely related species such as sorghum and maize. Reduced levels of microcolinearity between these species, in particular, have frustrated the use of rice as an intergenomic cloning vehicle to isolate disease resistance genes.

2.5 Gene Families

Analysis of the complete *Arabidopsis* genome sequence has made it possible to identify the genomic position of entire gene families and to reconstruct their evolution. For example, putative disease resistance genes are unevenly distributed across the 5 chromosomes of *Arabidopsis*. There are 50 on chromosome 1; 7 on chromosome 2; 17 on chromosome 3; 32 on chromosome 4; and 60 on chromosome 5. The genes are arranged as single gene loci, clusters, and superclusters. The large number of genes in this family resulted from an ancient duplication of the genome and subsequent rearrangements. (This is likely to be the case for all large gene families in *Arabidopsis*.) Subsequently, a few ancestral genes underwent local amplifications, leading to tandem gene pairs, some of which were broken up by mechanisms such as chromosomal translocations, while others produced clusters or superclusters as a result of further amplifications. Understanding the evolution of gene families helps account for the low levels of colinearity observed between plant lineages such as *Arabidopsis* and rice. Despite these differences, however, it is interesting to note that the rice genome contains putative orthologs of nearly all genes known to control disease resistance responses in *Arabidopsis*. This suggests that, despite high levels of genomic rearrangement since their divergence some 200 million years ago, there remains extensive conservation of disease resistance signaling between the dicots and monocots.

2.6 Genome Plasticity

Comparative genome studies have demonstrated that plant genomes are highly dynamic. Amplifications, such as those described for disease resistance gene clusters, are thought to result from intra- and intergenic recombination and gene conversion. Chromosomal duplications, deletions, inversions, and translocations also occur frequently, and transposons may be major mediators of genome expansion and contraction. For instance, a large inversion of about 700 kb relocated pericentromeric regions to an interstitial

position on the short arm of chromosome 4, where it forms a heterochromatic knob.

In addition to rearrangements within the nuclear genome, lateral gene transfer from endosymbionts has played a significant role in the architecture of the plant nuclear genome. It has been estimated that as much as 18% of the *Arabidopsis* genome is derived from cyanobacteria, and that even recent integrations of chloroplast (derived from cyanobacteria) and mitochondrial DNA (derived from α-proteobacteria) have occurred. The *Arabidopsis* genome revealed 17 different transfer RNA- and intron-containing insertions of chloroplast DNA as well as a complete copy of the 367-kb mitochondrial genome near the centromere of chromosome 2. Evidence of these events have also been observed in rice and humans with 59 fragments of mitochondrial DNA >2 kb inserted in the human genome. In plants, these lateral gene transfers have recently been demonstrated in the laboratory, suggesting that this type of phenomenon occurs relatively frequently. It is interesting to note that chloroplast genomes encode only 50 to 200 proteins, while cyanobacterial genomes, from which the chloroplast originated, encode several thousand proteins. This reduction has been made possible by the nuclear acquisition of genes from the organelle. Subsequent evolution has provided the necessary targeting signals to allow these nuclear-encoded proteins to be synthesized on cytoplasmic ribosomes and reimported into the organelles.

3 Genome Function

Although the *Arabidopsis* genome has not demonstrated a high level of synteny with other plant genomes, it has been remarkably successful as a tool for identifying gene function. Despite the potential for functional redundancy, *Arabidopsis* has provided (and will continue to provide) an excellent reference organism for functional genomics. The function of 69% of genes can be classified according to sequences similar to proteins of known function in other organisms. However, the function of only 9% of genes has been determined experimentally (The *Arabidopsis* Genome Initiative).

The current challenge is to assign a function to the approximately 8000 genes with completely unknown function, and to verify the true functions of the more than 15 000 genes that have been assigned functions by analogy with other organisms. Even the approximately 2000 genes, whose functions have been identified experimentally, may have additional, for example, stage-specific, functions of which we are unaware. The challenge is to discover novel methods by which to unravel the secret life of plants.

3.1 Loss-of-function

Classically, genetic pathways have been dissected using screens for loss-of-function mutations that disrupt a single gene, thus revealing its function. This type of analysis is collectively known as *forward genetics*. Loss-of-function mutations can be created in a number of ways, including chemical mutagens, physical mutagens, or biological mutagens, such as T-DNA (transfer DNA) or transposable elements. The role of genes, for example, in disease resistance, development, signal transduction, membrane transport, and light perception has all

been inferred from the analysis of mutant phenotypes.

3.2 Classical Mutants

Classical loss-of-function mutations are frequently induced by chemical (most commonly ethyl methanesulfonate [EMS]) or physical mutagens such as radiation (X ray, γ ray, or fast neutron). EMS mutants often produce G to A transitions, while fast neutrons usually produce small deletions. Mutagenesis using EMS is the most commonly used method since it is efficient and generates a wide range of mutant phenotypes. These phenotypes identify varying degrees of disrupted gene function, providing complete loss of function, weak, dominant, or conditional alleles. These mutant alleles can be used in a variety of ways to further characterize the function of a gene, for example, weak alleles of mutant genes can be used to identify second site modifiers, which either enhance or suppress the primary phenotype. The disadvantage of EMS, however, is that it generates many mutations within the genome and extraneous mutations must be removed by repeated backcrossing to wild type. Additionally, genes that act redundantly cannot be identified in loss-of-function screens. Furthermore, the only way to isolate the mutant gene is by the tiresome task of positional cloning. Positional cloning, however, is no longer the technically demanding task it was in the 1990s. As a result of the complete genome sequence and the extensive number of molecular markers that are available, the procedure is now routine. Ultimately, a mutant gene is identified by the complementation of the mutant phenotype with the wild-type gene, or the molecular analysis of several independent mutant alleles. Fast neutron mutagenesis often results in small deletions, which make positional cloning even easier, since DNA blot hybridization, rather than DNA sequencing, can be used to identify the mutated gene.

3.3 Insertional Mutants

In contrast to EMS or fast neutron mutagens, insertional mutagens, such as defined T-DNAs or transposable elements can be used as a tag to identify the *Arabidopsis* genomic DNA that flanks them (gene tagging).

3.3.1 T-DNA

The T-DNA of *Agrobacterium*-mediated plant transformation vectors is used as a powerful insertional mutagen. T-DNA insertions occur randomly in the *Arabidopsis* genome, usually generating loss-of-function mutations. The relationship between the mutation and the T-DNA insertion can be verified simply by screening for co-segregation of the mutant phenotype with the marker gene on the T-DNA. As many mutants generated by this strategy are not tagged, the disrupted gene must be used to complement the mutant phenotype to confirm its function. The disadvantage of T-DNA insertions is that the number of mutations induced in each plant line is low (1 or 2), as compared to EMS (where 100 or more lesions are induced per genome). Thus, a much larger T-DNA-mutagenized population must be screened to reach levels of saturation similar to those obtained using EMS. High-efficiency transformation procedures have allowed the generation of large populations of T-DNA insertion lines over recent years.

3.3.2 Transposons

Transposons are an alternative to T-DNAs for the production of insertional mutations. Here, a tagged mutation can be verified by the remobilization of the transposable element, which restores the mutant phenotype to wild type, thus avoiding the need for complementation. Transposon insertion screens can make use of endogenous or heterologous transposable elements.

The most popular endogenous transposable element, *Tag1*, was first identified as an insertion in the nitrate transporter gene *CHL1* of *Arabidopsis*. This element was found in Landsberg *erecta*, but not in the Columbia or Wassilewskija accessions. *Tag1* is an autonomous element capable of independent excision. Its activity is restricted to developing male and female gametophytes, which means that excision events are predominantly germinal. Germinal excision is important for gene tagging since this determines the number of potentially useful heritable mutagenic events. Endogenous elements also account for at least 10% of the *Arabidopsis* genome (one-fifth of the intergenic DNA), but these are generally silenced (The *Arabidopsis* genome initiative, 2000). Heterochromatic regions are rich in transposable elements and evidence is accumulating that heterochromatin was derived from euchromatin by the insertion of transposable elements. Heterochromatic regions contain methylated DNA and other forms of chromatin modification that are thought to regulate the mobility of transposons. Although transposons are frequently silenced by methylation, active transposons have also been found in plants, most famously in maize.

When transposon tagging was under development in *Arabidopsis*, very few endogenous elements had been characterized, and this led to the introduction of heterologous transposable elements from other species. Maize elements, *Activator/Dissociation* (*Ac/Ds*), and *Enhancer/Inhibitor* (*En/I*), also known as *Suppressor-mutator* (*Spm*), are among the most popular of these heterologous elements. *Ac/Ds* has been widely used to great effect in a number of plant species, including tomato, tobacco, and *Arabidopsis*. In *Arabidopsis,* effective levels of transposition of *Ds* (a nonautonomous element) were achieved using a stabilized *Ac*-expressing transposase under the 35S promoter. Using this system, the *Ds* element is transposed when, by crossing plants, the *Ac* transposase is supplied *in trans*. Studies have shown that somatic excision, as a result of the constitutive expression of the 35S *Ac* transposase, occurs frequently, and that *Ds* transposition is often linked to the donor site (68% of transpositions). This linked transposition provides a clear advantage over T-DNA insertions in targeted strategies; it allows the transposition of *Ds* from launch sites close to the target locus. To prevent excision of the *Ds* element after transposition, *Ac* is usually segregated away, thereby generating stable insertions. Nevertheless, some insertional mutants may lose their *Ds* tag prior to stabilization. The *Ac/Ds* system has been used on many occasions to identify gene function in *Arabidopsis*, as has the *En/Spm* system.

3.3.3 Enhancer Detection and Gene Trapping

The spatial and temporal control of gene expression is mediated by *cis*-acting elements and *trans*-acting transcriptional regulators that bind in a sequence-specific manner. Such elements were first revealed through analyses in which promoter fragments were fused to a reporter gene.

Enhancer detection is a method that was first developed in *Drosophila*, allowing the identification of such *cis*-regulatory elements (enhancers) in the genome. The method, which relies on a mobile genetic element carrying a reporter gene under a weak promoter that can be influenced by nearby regulatory sequences, allows the identification of genes based on their pattern of expression. A modification of this approach, gene trapping, which relies on the generation of transcriptional fusions between the endogenous gene and the introduce reporter gene, was then quickly developed for mice. Both approaches were adapted to *Arabidopsis*, either using T-DNA or *Ds* elements that contain a reporter gene, encoding either beta-glucuronidase (GUS) or the green fluorescent protein (GFP). The expression of the reporter gene depends on the flanking *cis*-acting signal sequences. These produce cell- and tissue-type specific expression patterns that can be used not only as molecular markers but also to provide clues as to the function of the associated gene.

3.4 Targeted Gene Disruptions

A number of multicellular model organisms have benefited from routine methods of targeted gene disruption (TGD), for example, mouse, the moss *Physcomitrella patens*, and *Drosophila*. Despite much effort, TGD approaches in *Arabidopsis* have proved inefficient. Even the targeted disruption of transgenes has been difficult. However, a method for assessing the efficiency of TGD in endogenous *Arabidopsis* genes has recently been developed. Results have shown that, while the frequency of disruption is indeed low, the actual number of events is sufficient for the isolation of a targeted mutant from the large number of transgenic seeds that can be obtained. Unfortunately, these methods are not yet routine, so the best current options are either to screen for local insertions into the gene of interest by a nearby transposable element or to take advantage of the expanding number of insertion mutants now available (http://enhancertraps.bio.upenn.edu/; http://genetrap.cshl.org/; http://www.biotech.wisc.edu/Arabidopsis/; http://www.mpiz-koeln.mpg.de/GABI-Kat/; http://flagdb-genoplante-info.infobiogen.fr/projects/fst/DocsIntro/introCollection.html; http://ukcrop.net/agr/insert.html; or http://nasc.nott.ac.uk/info/slat_info1.html). These approaches, together with genome sequence data, have provided an invaluable resource for reverse genetics. Insertional mutants can be screened by PCR, or by BLAST-searching a gene of interest against the DNA sequences that are identified adjacent to the insertion site. Several collections of insertion lines can be screened for known insertions in a gene of interest. Knowing the complete sequence of the genome has made an alternative reverse genetics approach very powerful. This approach, known as *TILLING* (Targeted Induced Local Lesions IN Genomes), combines high-density point mutations, provided by traditional chemical mutagenesis, with sensitive detection methods. This allows mutations in a particular gene of interest to be identified, so that genes of unknown function can be targeted. The real advantage here is that a series of mutant alleles can be produced, including weak or possibly conditional alleles; whereas insertional mutants tend to be knockouts. This means that the function of essential genes can be studied as a result of identifying nonlethal mutant alleles.

3.5 Microarrays

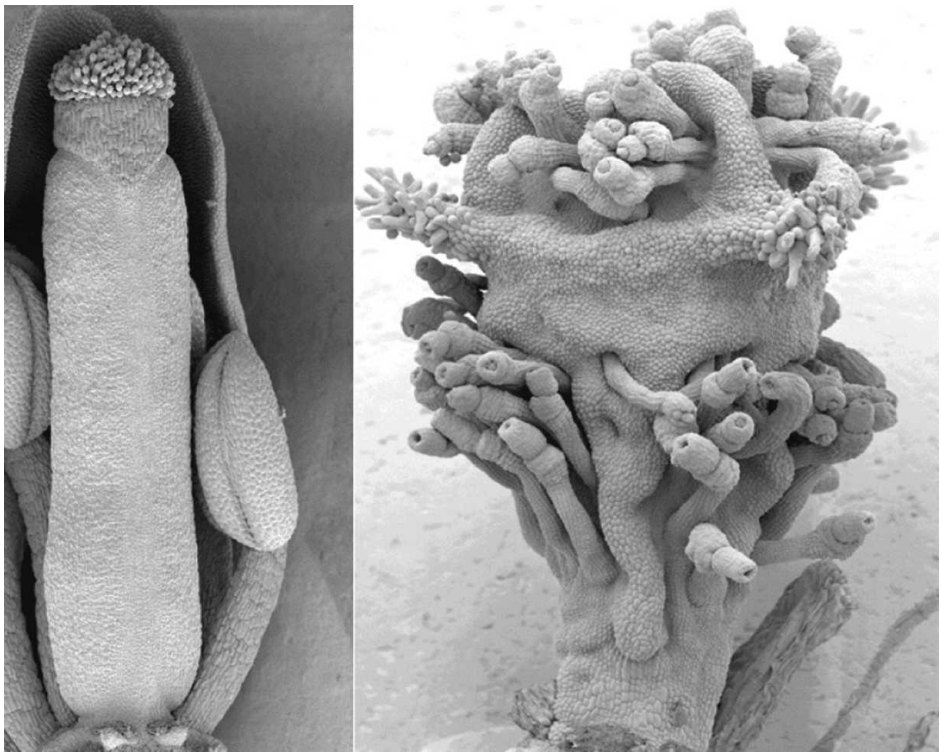
A powerful experimental approach to help elucidate the function of the large numbers of genes that have been identified from the genome sequence is to use gene chips or microarrays. These tools allow the systemic analysis of expression profiles of large numbers of genes, including stress-induced, tissue-specific, or developmentally regulated genes. DNA microarrays are constructed either from cDNA expressed sequenced tags (ESTs), gene sequences, or gene-specific oligonucleotides. These systemic experimental approaches have generated large data sets that can be used to identify genes that have similar expression profiles under specific conditions or identify genes that are expressed at similar developmental stages. They can even be used to identify the expression of genes that are restricted to a small subset of cells. The advantage of this type of analysis is that candidate genes with parallel regulation to known genes that are involved in specific responses or developmental processes can be identified. These candidate genes must be further analyzed to determine their specific role in the plant function of interest. This type of analysis can also be used to identify common *cis*-acting regulatory elements in genes that are regulated in parallel. For example, 450 circadian-regulated genes were identified in *Arabidopsis* using microarrays. Comparative promoter sequence analysis of these genes revealed a nine-nucleotide ''evening element'', which was shown to be required for circadian control of gene expression. Similarly, genes may be identified that are involved in several responses, for example, in the stress responses to drought, cold, and high-salinity, highlighting cross talk between regulatory networks.

The combination of chip analysis with mutational analysis to identify downstream target genes of regulatory complexes is another powerful approach. Using this technology, differences in the expression profiles of the mutants *mea, fie* (components of the MEA/FIE Polycomb Group [PcG] complex) and wild-type plants were identified during early embryogenesis, revealing that two genes, *PHERES1* and *MEIDOS*, were significantly deregulated in these mutants. One of these candidate genes, *PHERES1*, was analyzed further, and, using chromatin immunoprecipitation, it was shown that its promoter region was bound directly by the MEA/FIE PcG complex.

3.6 Gain-of-function Mutations

Identifying the function of genes in large gene families often presents problems, especially if these genes act redundantly. Loss-of-function mutations in redundantly acting genes are frequently overlooked. For instance, the *kanadi1* (*kan1*) and *kanadi2* (*kan2*) single mutants show no visible phenotype in *Arabidopsis*, but together lead to loss of polarity in lateral organs. In the double mutants, abaxial cell types are replaced by adaxial cells in most lateral organs, most strikingly in reproductive tissue, leading to radial development of ovules (Fig. 3). Similarly, a triple mutant of the TGA family of transcription factors, *tga6*, *tga2 tga5*, blocks salicylic acid-induced pathogen-related gene expression and disease resistance, but not single or double mutant combinations.

Another way to identify the function of redundantly acting genes is to express them ectopically. In this way, a mutant phenotype can be produced if the ectopic



(a) (b)

Fig. 3 *kanadi* loss-of-function phenotypes. (a) In the wild-type *Arabidopsis* gynoecium, ovules are restricted to the internal (adaxial) side. (b) In *kan1 kan2* plants polarity is lost so that the placenta develops externally and ovules develop radially around the entire abaxial circumference of the ovary and on its distal end. (Eshed, Y., Baum, S.F., Perea, J.V., Bowman, J.L. (2001) Establishment of polarity in lateral organs of plants, *Curr. Biol.* **11**, 1251–1260.) Reproduced with permission from Elsevier.

expression of a gene deregulates a genetic pathway. Again, with the *KANADI* genes, single gene knockouts show no phenotype; however, the ectopic expression of either *KAN1* or *KAN2,* throughout leaf primordia, results in the dramatic transformation of adaxial to abaxial cell types. Several strategies to achieve a gain-of-function phenotype in plants have been devised.

3.6.1 **Constitutive Ectopic Expression**

The simplest approach is to place a gene under the transcriptional control of a constitutive promoter such as the CaMV 35S promoter. This type of analysis has been the basis of many gene function studies. For instance, overexpression of the floral homeotic gene *APETELA3* (*AP3*), under the control of the 35S promoter, showed the positive regulatory interaction between *AP3* and *PISTILLATA* (*PI*) in floral development (Fig. 4).

The ectopic expression of genes in one species can result in a phenotype reminiscent of another species, leading to

(a) (b)

Fig. 4 Phenotype of *Arabidopsis thaliana* flowers. (a) Wild type, showing sepals (whorl 1), petals (whorl 2), stamen (whorl 3), carpels (whorl 4). (b) Overexpression of *AP3* (*35S::AP3*) showing sepals (whorl 1), petals (whorl 2), stamen (whorl 3), stamen (whorl 4). *PI* is expressed in whorls 2, 3, and 4, early in floral development, but not in whorl 1. Ectopic expression of *AP3* in all whorls causes additional *PI* expression to be maintained in whorl 4, showing a positive regulatory reaction between *AP3* and *PI* in floral development. In wild-type flowers, *AP3* is only expressed in whorls 2 and 3, so that *PI* expression in late floral development is maintained only in whorls 2 and 3. (Jack, T., Fox, G.L., Meyerowitz, E.M. (1994) *Arabidopsis* homeotic gene APETALA3 ectopic expression: transcriptional and post-transcriptional regulation determine floral organ identity, *Cell* **76**, 703–716.) Reproduced with permission from Elsevier.

the identification of genes that play a role in the evolution of developmental pathways. Ubiquitous overexpression of the *Knotted*-class homeobox gene *KNAT1* (usually restricted to the shoot meristem), resulted in highly abnormal leaf morphology that included severely lobed leaves. The morphology of leaves is a prominent characteristic of different plant species. In plants with simple leaves, the *KNOTTED1*-like genes are expressed in the shoot apical meristem (SAM) and are downregulated in leaves. In many plants with complex leaves, it was found that *KNOTTED*-like genes are expressed late in leaf development. The gene in *Arabidopsis* responsible for downregulating *Knotted*-class genes is *ASYMMETRIC LEAVES1* (*AS1*), encoding a MYB-domain protein closely related to *PHANTASTICA* in *Antirrhinum* and *ROUGH SHEATH2* in maize. Downregulation of the *PHANTASTICA*-like MYB transcription factor in leaves seems to have been an important factor in the evolution of different leaf forms in plants. These discoveries have demonstrated that altered gene expression patterns contribute to the diversity of plant morphology. Another well-documented example is found in flowers. Here, the expression domains of the MADS-box proteins have contributed to the diversity of floral morphology found among the angiosperms. The mis-expression of genes is, therefore, a powerful tool for determining gene function and can identify candidate genes that may be responsible for the development of diverse morphologies over evolutionary time.

Several alternative approaches to misexpress genes have been developed that allow the activation of randomly tagged genes. These include specialized transposable elements that place a constitutive promoter upstream of genes as a result of random integration of transposons. This type of gain-of-function approach was pioneered by Coupland and colleagues. The technique allows ubiquitous ectopic expression of activation-tagged genes. Using this technique, however, genes essential for regulating early embryonic and gametophytic pathways may be lost, since the ubiquitous ectopic expression of these genes may produce a lethal effect. In addition, the ubiquitous ectopic expression may mask any tissue-specific effects that may be identified when deregulated gene expression is restricted to certain cell types. An alternative T-DNA-based system that contains multimerized transcriptional enhancers from the *CaMV 35S* gene has been developed. Using this approach, it appears that the expression pattern of endogenous genes is maintained; however, the level of expression is enhanced. This approach has not only been useful in identifying the function of genes but has also helped identify mechanisms that regulate the accumulation of specific mRNAs that are required for normal development. MicroRNAs downregulate their target genes either by cleaving the mRNA or by blocking their translation. Using this activation-tagging technique, specific expression of microRNA from the *JAW* locus was enhanced, revealing its role in targeting the mRNAs of a family of transcription factors for cleavage. These mRNAs encode the TCP domain transcription factors involved in leaf development, providing tangible evidence that microRNAs provide an endogenous mechanism of gene silencing that specifically regulates aspects of plant morphogenesis.

3.6.2 Inducible Ectopic Expression

The generation of mutants in critically important genes inevitably results in lethality. To overcome early lethality problems, inducible tagging systems have been devised. These rely on heat shock or chemical induction, so that ectopic gene expression can be controlled temporally. Using a chemically inducible activation-tagging system, the *WUSCHEL* gene, a homeodomain transcription factor normally restricted to the central zone of the SAM and nucellus tissue of the developing ovule primordium, was misexpressed, allowing ectopic embryo development in roots (Fig. 5). Here, the effect of gene expression is tissue-specific and demonstrates the importance of gene regulation to restrict expression to a particular subset of cells. An example demonstrating the value of restricted ectopic gene expression to very small regions of tissue (fractions of a meristem) is the induced ectopic expression of expansin in the meristem, leading to the formation of leaves. This will be of particular importance when attempting to deregulate gene expression in studies on the evolutionary development of reproductive strategies in plants. *Arabidopsis* reproduces sexually; however, it is generally accepted that apomictic reproduction (clonal reproduction through seed) results from the deregulation of sexual processes, since apomicts are derived from sexual ancestors. These rapid alterations in gene expression are thought to result from epigenetic effects, frequently produced by ploidy changes that result from interspecific hybridization. Further development of tissue-specific inducible gene activation may reveal candidate genes, whose altered gene expression patterns can account

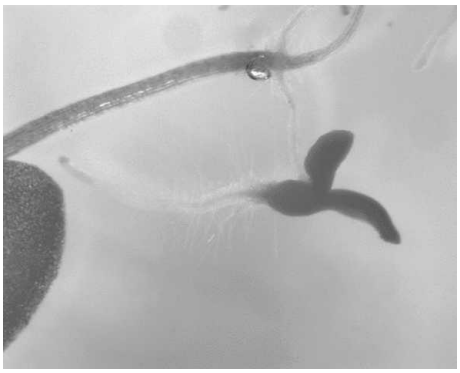


Fig. 5 Misexpression of a gene that controls stem cell identity (*WUSCHEL*) can be used to redirect root cells of an intact plant to any of the other major sporophytic developmental pathways, depending on additional cues, for example, leaf development (without additional cues), floral development (together with LEAFY), or embryogenesis (in response to increased auxin) (Gallois, J.L., Nora, F.R., Mizukami, Y., Sablowski, R. (2004) WUSCHEL induces shoot stem cell activity and developmental plasticity in the root meristem, *Genes Dev.* **18**, 375–380.) for changes in the reproductive pathway of plants.

4 Gene Regulation

The regulated expression of genes allows an organism to respond to environmental cues, to develop, and to reproduce. These mechanisms of gene regulation involve more than 12% of *Arabidopsis* genes. Gene expression is controlled, both spatially and temporally, through specific interactions of transcription factors with their DNA recognition sequences, and through the dynamic restructuring of chromatin, which alters the accessibility of the DNA to these factors.

4.1 Transcription Factors

There are more than 1500 transcription factors encoded by the *Arabidopsis* genome, which account for about 6% of the predicted total number of genes. The *Arabidopsis* genome encodes diverse families of transcription factors, many of which are unique to plants, for example, the WRKY, NAC, and AP2/EREBP families. Others factors are present in families that are common to plants, fungi, and animals. However, in plants, these families have grown to include large numbers of genes. Two such super families are those of the MYB and MADS transcription factors. The MYB factors comprise one of the largest families with approx. 190 MYB and MYB-related genes identified in *Arabidopsis*. A similar number, 156, have been identified in rice. In contrast, the corresponding family in yeast has only 10 members, *Drosophila* has 6, and *Caenorhabditis elegans* only 3. A similar pattern emerges for the MADS-box genes; *Arabidopsis* has 107, rice has 71, yeast has 4, and *Drosophila* and *C. elegans* have only 2 each. This type of comparative genome analysis, between *Arabidopsis*, rice, yeast, *C. elegans*, and *Drosophila*, has identified differences in the relative size of many other gene families, revealing that plants and animals have developed different regulatory mechanisms since their divergence to achieve similar processes. In both animals and plants,

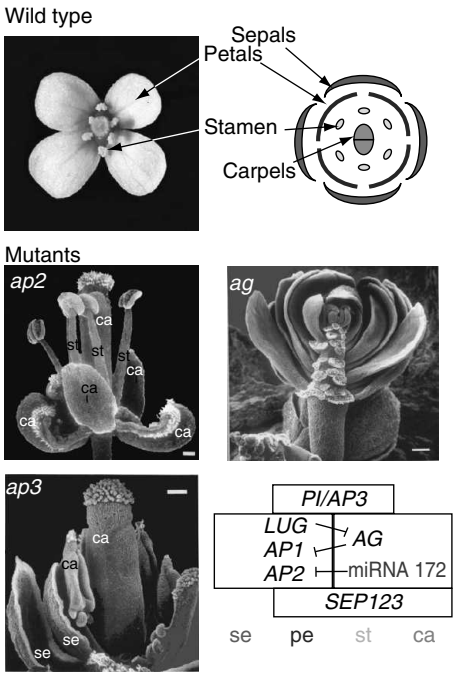

Fig. 6 The ABC model was proposed after the analysis of phenotypes of homeotic floral mutants. Floral organ identity is hypothesized to result from the combined activity of 3 classes of homeotic gene products. A function (*AP1* and *AP2*) = sepals, A + B (*AP3* and *PI*) function = petals. B + C (*AGAMOUS*) = stamens, and C function alone = carpels. Loss-of-function alleles of these genes result in homeotic transformations; for example, in *ap2* mutants, carpels develop in the position of sepals and stamen in the position of petals. In *ag* mutants, petals develop in the position occupied by stamen, and another flower meristem replaces the carpels. In *ap3* mutants, sepals replace petals and carpels replace stamen. In triple mutants, the floral organs form leaf-like structures; however, leaves are not converted to floral organs unless a *SEP* gene is expressed in addition. Other factors restrict the spatial activity of the A, B, and C class genes. The spatial activity of the A, B, and C class genes are controlled so that *AP2* and *LEUNIG* restrict the activity of *AG* to whorls 3 and 4. *AG* restricts the activity of *AP1* to whorls 1 and 2. *SUPERMAN* (not shown) prevents the activity of B class genes in whorl 4 and a microRNA, *miR172*, prevents the translation of *AP2* mRNA in whorls 3 and 4. The *ap2* SEM reproduced from Bowman et al. (1991) with permission from Development and the company of Biologists; the *ag* SEM reproduced from Bowman and Meyerowitz (1991) with permission from the company of Biologists; and the *ap3* SEM reproduced from Bowman, Smyth and Meyerowitz (1989) (*Plant Cell* **1**, 37–52, with permission from the American Society of Plant Biologists).

for example, the position and specification of organs is an essential prerequisite for normal development. In animals, this patterning is achieved by the localized activity of members of the homeobox gene family, which determines the spatial arrangement and proper positioning of organs, such as limbs. In plants, however, the specification of floral organ positioning and identity (sepals, petals, stamens, carpels) is reliant on the domain-specific expression of members of the MADS-box family (Fig. 6). Although both plants and animals follow the same basic concept (combinatorial gene regulation) to specify and position organs, they use distinct families of transcription factors, despite the fact that they both have homeo- and MADS-box genes. This divergence is further emphasized by the absence of certain transcription factor families from various lineages, as described earlier.

4.2 Epigenetics

Frequently, the development of technology to identify gene function has led to new discoveries in gene regulation. Inactivation of gene expression was an unexpected result of the insertion of multiple copies of transgenes for ectopic expression. This led to the first investigations into gene silencing in multicellular organisms using sense or antisense transgenes that were shown to downregulate target gene expression. Manipulations with antisense

genes have served as tools to determine the mechanisms of gene function in many aspects of the plant life cycle, including floral development and disease resistance. Although gene silencing has served as an alternative means by which to phenocopy the effect of mutants, it has also allowed the genetic analysis of silencing mechanisms.

Using plant lines with silent transgenes, it has been possible to show that specific gene inactivation can occur, either at the transcriptional level (transcriptional gene silencing, TGS), or posttranscriptionally (posttranscriptional gene silencing, PTGS), as a result of specific mRNA degradation. Mutant screens that identified plant lines with reactivated transgene expression produced lesions in genes that are involved in silencing. Using this type of approach, it was discovered that mutations in *ddm1* (decrease in DNA methylation) cause the activation of silenced transgenes. The *DDM1* gene encodes a SW12/SNF2 chromatin-remodeling factor. When this gene is mutated, cytosine methylation of DNA is reduced by 70%, with most immediate effects in repeated sequences, and also affecting dispersed sites upon inbreeding, causing progressive heritable developmental abnormalities. Reductions in the methylation of repetitive sequences lead to the reactivation of transcriptionally silent transposable elements and silenced endogenous genes.

Cytosine methylation at symmetric CG nucleotides is an evolutionarily conserved DNA modification that has been found in vertebrates, plants, and some fungi. In addition, plants have significant levels of cytosine methylation at non CG-sequences, including symmetrical CNG and asymmetrical CNN sequences. DNA methylation is established and maintained by a variety of DNA methyltransferase genes (at least 10 encoded by the *Arabidopsis* genome). In animals, the methylation signal is recognized by methyl-CpG-binding domain (MBD) proteins (there are at least 12 putative MBD proteins in *Arabidopsis*). In animals, these proteins recruit a variety of histone deacetylase-(HDAC) and chromatin-remodeling complexes, which lead to heterochromatin formation and transcriptional silencing. In the *Arabidopsis* mutant *flowering locus d* (*fld*), the expression of the repressor *FLOWERING LOCUS C* (*FLC*) (a MADS-box transcription factor that blocks the transition from vegetative to reproductive development) is elevated, resulting in late flowering. FLD is a plant homolog of the human protein KIAA0601, a component of the human histone deacetaylase 1,2 (HDAC1/2) corepressor complex. In the *fld* mutant, the *FLC* locus contains nucleosomes in which histone H4 is hyperacetylated. FLD therefore regulates flowering time in *Arabidopsis* by altering chromatin architecture; deacetylation of histone H4 causes condensation of chromatin to produce transcriptionally inactive heterochromatin. The N-terminal tails of histones can be subjected to a variety of posttranslational modifications, including phosphorylation, ADP-ribosylation, sumoylation, methylation, as well as acetylation. Interestingly, the *FLC* gene also undergoes dimethylation at lysine 9 and lysine 27 on histone H3 during vernalization (an extended period of cold treatment required for floral induction). These methylation marks are applied by a Polycomb complex that has histone methyltransferase activity toward histone H3. Methylated H3 histones at the *FLC* locus cause stable repression of *FLC* after vernalization, thus allowing the induction of flowering. It is known that maintenance DNA-methyltransferases perpetuate existing DNA methylation in CpG

sequences after DNA replication by methylating hemimethylated sites. Less is known about the way in which unmethylated DNA loci are initially targeted for methylation and gene silencing. This type of gene silencing is required by plants to defend against invading viruses and transposable elements, and is directed at repetitive sequences, suggesting a homology-based trigger for DNA methylation. In plants, the first clues that this phenomenon may be caused by RNA came from the observation that RNA viroids cause *de novo* cytosine methylation of homologous genomic DNA sequences. Among the candidate methyltransferase genes encoded by *Arabidopsis* for *de novo* DNA methylation are the domain rearranged methyltransferases (DRMs), which share homology with the mammalian *Dnmt3* genes, which encode *de novo* methyltransferases. Recently, DRMs have been shown to be involved in RNA-directed DNA methylation (RdDM). Significantly, mutations in *dicer-like3* (*dcl3*), *RNA-dependent-RNA-polymerase2* (*rdr2*), *silencing defective4* (*sde4*), and *argonaute4* (*ago4*) have been shown to affect DRM-dependent *de novo* methylation of a *FWA* transgene and endogenous *FWA* locus. Interestingly, *DCL3*, *RDR2*, and *AGO4* are homologs of proteins involved in RNA silencing. RNA silencing uses 21- to 25-nucleotide small interfering RNAs (siRNA) to direct mRNA cleavage or induce transcriptional gene silencing. This type of RNA-induced gene silencing has been exploited in plants to silence target genes. Single-stranded hairpin RNAs (hpRNAs), or dsRNAs, are used in an approach known as *RNAi* (RNA interference). Vectors producing dsRNA are introduced into a plant, where an RNase III–like helicase (Dicer) specifically cleaves the dsRNA into siRNA. The siRNAs are incorporated into a nuclease-containing complex called *RISC* (RNAi silencing complex – *ARGONAUTE* is a component of RISC), which degrades any mRNA that is complementary to the single-strand siRNA associated with the complex. The siRNA also targets homologous DNA sequences for *de novo* methylation by *DRM1* and *DRM2*.

RNAi constructs designed to silence endogenous genes can be made simply, using a variety of vectors, and can be stably expressed in plants following *Agrobacterium*-mediated transformation or transiently expressed following bombardment. The advantage of a homology-based system of gene silencing is that, using this technique, gene families can be silenced so that a mutant phenotype can be obtained, even when genes act redundantly. Interestingly, PTGS or RNAi silencing in plants can propagate, after the initiation of local silencing, from cell to cell through plasmodesmata (continuous cytoplasmic bridges between cells) and over long distances through the vascular system, causing sequence-specific degradation of transcripts systemically (Fig. 7). Thus, RNAi is an extremely powerful method for analyzing gene function. However, because of its systemic nature, tissue-specific knockdown of genes tend to be unsuccessful. A further disadvantage of gene knockdowns using RNAi is the potential instability of the RNAi effect. This is most likely caused by transcriptional silencing of the RNAi construct itself.

4.3 Cellular Communication

The function of many genes in plants is to communicate between cells. Cell

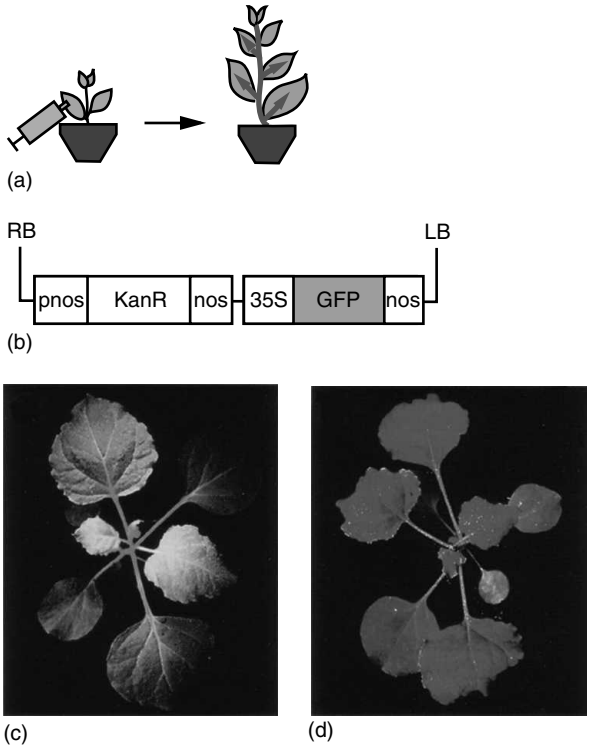

Fig. 7 Posttranslational gene silencing of a GFP transgene, induced by infiltration with *Agrobacterium tumefaciens*. Schematic representation of the experiment (a). Transgenic *Nicotiana benthamiana*, containing a T-DNA (b), and expressing GFP, was infiltrated with a hypervirulent strain of *A. tumefaciens* carrying the same T-DNA. Prior to infiltration, the plants show high levels of GFP expression under UV illumination (c). Ten days after infiltration complete GFP silencing was achieved (d). Plants appear uniformly red as a result of chlorophyll fluorescence under UV illumination. (Brigneti, G., Voinnet, O., Li, W.-X., Ji, L.-H., Ding, S.-W., Baulcombe, D.C. (1998) Viral pathogenicity determinants are suppressors of transgene silencing in *Nicotiana benthamiana*, *EMBO J.* **17**, 6739–6746.) Reproduced with permission from Nature Publishing Group. (See color plate p. xxv.)

communication can involve short- or long-range signals that usually operate via ligand–receptor interactions that initiate intracellular signal transduction cascades, much as they occur in animal systems. There is, however, an intercellular cell-to-cell signaling system unique to plants that is based on plasmodesmata, which are thought to be involved in the trafficking of endogenous proteins, such as transcription factors, and are used by viruses for cell-to-cell spread. KNOTTED in maize, for example, has been shown to move to cells in which its RNA is not present. Mosaic

analysis is frequently used to determine whether the function of a protein is cell autonomous, or whether it has a role in cells where it is not expressed (noncell autonomous). This can be achieved in a number of ways using methods that rely either on transposons or on recombinases. The induced excision of a *Ds* element by *Ac*, or an intervening sequence by recombinases, can restore the wild-type function of a gene in a few cells of a plant. Therefore, the plant will be a chimera, containing cells of different genotypes. Using these techniques, it has been shown that APETALA3 (AP3) can regulate cell fate autonomously, while acting nonautonomously to control organ shape and size. Similarly, LEAFY (LFY) can move to adjacent cells, activating target genes, while APETALA1 activates early target genes cell autonomously. These powerful tools can be used to determine a gene's mode of action, which would not be possible by simply examining the genomic sequence. It may be possible to make predictions as to whether a protein encoded by a gene is involved in cell–cell communication, but the precise mechanism or functional significance can be determined only through experimentation.

5 Conclusions and Future Prospects

Plants are a key element of sustainable environments, they provide the oxygen we breathe and are the producers at the source of the food chain. They have played this important role for millions of years and have a tremendous influence on our weather and climate. Plant resources, and the way in which they are managed, have enormous implications for our future well-being. Careful crop management can provide a solution to famine and disease, but must also play a role in averting the current global warming crisis. In the next few decades, we must reverse our dependency on fossil fuels and grow plants for the sustainable production of oils and plastics. Plant biotechnology involves the modification of plant performance. In relation to crops, this includes increasing yield, enhancing tolerance to stress, and increasing disease resistance. Breeding high-yield, dwarf, disease-resistant wheat and rice varieties has significantly increased world grain production. However, these yields must continue to climb if food production is to keep pace with increases in world population. One way in which yields can be increased to keep pace with rising populations is to identify and manipulate the activity of genes that affect economically important traits. These modifications may be achieved by increasing or decreasing the activity of genes that are naturally present in an organism. The genes, and the techniques by which these genes can be alternately regulated, are frequently identified in model organisms like *Arabidopsis* and then transferred to crop species. A major advantage of genetically modifying organisms is that plants can be exploited, not only as sources of food but also as sources of industrial raw materials, such as oils, starches, and biodegradable plastics. They can even be engineered as bioreactors for the production of vaccines and therapeutic antibodies, or as tools for bioremediation and mopping up pollutants such as heavy metals from contaminated soils. In order to achieve these aims, a thorough and broad understanding of plant biology, in all its fields, is indispensable. This understanding will be most efficiently achieved through the continued use of model organisms.

The Thale Cress *Arabidopsis thaliana* has proved an excellent model organism for the study of many aspects of plant biology. Its small genome, and the abundance of polymorphisms between the two most commonly used accessions has made it ideal for positionally cloning mutant genes. *Arabidopsis* was initially selected as a model organism because of its small size, its ease of growth, short life cycle, and fecundity. Over the last few decades, it has emerged as an invaluable and versatile tool for the plant biologist. It possesses many features that could not have been predicted by its early proponents, including its small genome and the ease with which it can be transformed. Today *Arabidopsis* is proving an excellent model for telomere and centromere studies, and has played a prominent role in unraveling the mechanisms of epigenetic gene regulation. *Arabidopsis* is not only the model organism at the forefront of plant biology but it also contributes to our wider understanding of the genomic structures and mechanisms in eukaryotic organisms as a whole. Even before the discovery of the structure of DNA, Laibach championed a model organism that has inspired a generation of scientists and has changed the face of biology.

Acknowledgments

Several thousand people work on furthering our understanding of how the information in the *Arabidopsis* genome is converted into growth and development, physiology and environmental interactions. Naturally, we could only give a glimpse of the wealth of information available for this reference plant and apologize to all colleagues whose work we did not cover in this chapter. We thank Claudia Köhler for helpful comments and critical reading of the entire manuscript and to Catherine Feuillet for helpful comments on the synteny section.

Keywords

Angiogenesis
The formation of new blood vessels.

Arteriogenesis
The growth of arterioles (preformed collaterals) into mature arteries.

Ischemia
A reduction in the blood supply to a bodily organ, tissue, or part; usually caused by constriction or obstruction of the blood vessels.

Myocardial Infarction
Destruction of heart tissue resulting from obstruction of the blood supply to the heart muscle.

Peripheral Vascular Disease (PVD)
A disease of the large blood vessels of the extremities. PVD may occur when major blood vessels in these areas are blocked and do not receive enough blood.

Reperfusion
The restoration of blood flow to an organ or tissue that has had its blood supply cut off, as after a heart attack.

Revascularization
A broad term that is usually used to describe surgical and catheter procedures that are used to restore blood flow to the heart or another ischemic organ. In the context of therapeutic angiogenesis, this term also encompasses the use of drugs, gene therapy, and stem cells.

Therapeutic Angiogenesis
The use of drugs or other therapeutic modalities to stimulate the revascularization of ischemic tissue.

Vasculogenesis
The *de novo* formation of blood vessels from angiopoeitic precursor cells.

Therapeutic angiogenesis refers to the use of drugs or other therapeutic modalities to stimulate the revascularization of ischemic tissue. The concept was first introduced by the German gynecologist Michael Höckel in 1989 as a therapeutic approach to improve regional tissue perfusion and viability following surgery. In the intervening two decades, there has been a virtual explosion of information relating to the growth factors and receptors involved, the molecular mechanisms of new vessel formation, the development of numerous animal models, and a number of clinical trials. The two major clinical indications are the coronary artery (ischemic heart disease) and peripheral vascular disease, but therapeutic angiogenesis could also be applied to wound healing.

Ischemic heart disease is the leading cause of death and the major contributor to morbidity in the Western world. This problem will continue to grow as the population ages and will be even more severe if the ''epidemics'' of obesity, metabolic syndrome, and diabetes continue to develop unchecked. In the United States alone in 1999 there were 1.1 million percutaneous coronary revascularizing interventions, 355 000 coronary bypass surgeries, and 131 000 endarterectomies. Annually, about 1.2 million Americans will have a first or recurrent coronary attack and roughly 502 000 of these people will die −340 000 of them in an ER or before they reach a hospital. It is estimated that 7.8 million Americans aged 20 years and older have survived a heart attack and about 6.8 million Americans have angina pectoris (chest pain or discomfort due to reduced blood supply to the heart). Moreover, within six years of a recognized heart attack, 18% of men and 35% of women will have a second heart attack. A significant number of these patients will die or be disabled with heart failure or the aftermath of a stroke. In the United States, coronary heart disease is the number one cause of premature permanent disability (19% of total) in the labor force (American Heart Association Heart Disease and Stroke Statistics – 2004 Update). Peripheral ischemic vascular disease is also a significant cause of major morbidity, affecting up to 14 to 18 million patients in the United States. In these patients, intermittent claudication (pain while walking that abates during rest) is the most common symptom. Other symptoms include numbness or weakness in the legs, aching pain in the feet or toes while at rest, nonhealing ulcers on the leg or foot, cold legs or feet, and skin color changes of the legs or feet. However, less than 20% of the patients with peripheral vascular disease have been diagnosed, and of those that are, many are often undertreated. Of these patients, more than 70% experience no change or any improvement in symptoms after 5 to 10 years of conservative management. However, 20 to 30% of patients develop more severe symptoms that require intervention, and a small fraction (less than 10%) will require amputation. Moreover, the 5 and 10-year rates of mortality can reach 30 and 50% respectively.

1 Revascularization

There are several interrelated processes that contribute to revascularization (Table 1). *Angiogenesis* refers to the development of new vessels; in the context of ''therapeutic angiogenesis,'' angiogenesis would be used to describe the proliferation of new capillaries in ischemic vascular beds. The primary driver of this angiogenesis is thought to be tissue hypoxia, which occurs as a consequence of poor tissue perfusion. The hypoxia sensor is believed to be a complex containing the oxygen-sensitive hypoxia inducible factor-1α (HIF-1α) subunit, which is rapidly destroyed in the presence of oxygen. In a reaction requiring oxygen and iron, a proline hydroxylase hydroxylates HIF-1α and makes it susceptible to ubiquitination by the von Hippel–Lindau protein and to subsequent degradation in the proteasome (Fig. 1). Genes of relevance to angiogenesis regulated by HIF-1α include vascular endothelial growth factor (VEGF), the VEGF receptor *flt*-1 (fms like tyrosine kinase-1; VEGFR-1), and angiopoietin-2 (Ang2). The products of these genes predominantly activate VEGF-dependent endothelial cell proliferation; interestingly the signals by other growth factors (e.g. fibroblast growth factors (FGFs), platelet-derived growth factors (PDGFs)) that are required for smooth muscle cell stimulation (necessary for support and stabilization of larger vessels) are not driven by hypoxia. However, the local growth of capillaries cannot compensate for ischemia because of the proximal occlusion of a major arterial vessel by an atheroma. Moreover, it is unclear whether tissue ischemia is really the primary driver of spontaneous revascularization.

Vasculogenesis is defined as the *de novo* formation of blood vessels from angiopoeitic precursor cells. This process is better known in embryonic development, where it describes the *de novo* formation

Tab. 1 Processes involved in new vessel formation and remodeling.

	Vasculogenesis	***Arteriogenesis***	***Angiogenesis***
Cell types involved	Endothelial precursor cells	Endothelial cells, smooth muscle cells, pericytes, monocytes	Endothelial cells pericytes
Primary stimulus	Developmental process; in adult not known	Inflammation shear stress	Inflammation ischemia
Product	Fully formed vessels (in embryo)	Arterioles/conduit arteries	Capillaries
Occurs in adult tissue	Minimal; unclear how important	Yes	Yes
Contribution to effective perfusion	Not clear; may contribute	Major contributor	Minor; important for local perfusion
Growth factors involved	VEGF, Ang-1, Ang-2, SDF1	PDGF, Ang-1, Ang-2, FGFs, MCP1	FGF1, FGF2, FGF4, FGF5, VEGF1, VEGF2, VEGF3, HGF, TGFβ

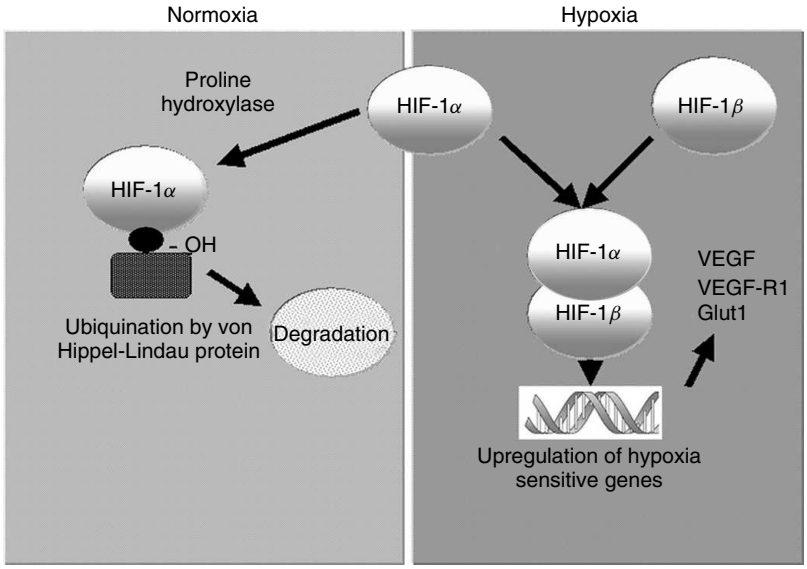

Fig. 1 The hypoxia sensor. The α-subunit of the transcription factor hypoxia-inducible factor 1 (HIF-1α) is hydroxylated by proline hydroxylase in the presence of oxygen and iron. It then undergoes ubiquitination by the von Hippel–Lindau protein and is then degraded by the proteasome. In contrast, under conditions of hypoxia, HIF-1α-levels increase and can interact with HIF-1β. The HIF-1 heterodimer can then bind to specific response elements on hypoxia-regulatable genes (e.g. VEGF, VEGFR-1, Glut1), leading to the upregulation expression.

of the vascular system from mesenchymal stem cells that form blood islands. However, there are a number of recent studies that suggest that bone marrow-derived cells could contribute to new vessel formation in the context of therapeutic angiogenesis.

Arteriogenesis by definition describes the growth of arterioles (preformed collaterals) into mature arteries. It may also be more broadly interpreted as the growth of new, larger vessels. Interestingly, the history of the study of collaterals and their functional importance predates early studies of angiogenesis and vasculogenesis by two to three centuries! Collaterals were first described by the English physician Richard Lower who pioneered transfusions from dog to dog and from lamb to man. He described coronary artery anastomoses on the basis of the observation that fluid injected into one artery flows into the other and concluded that "there is a need of vital heat and nourishment, so deficiency of these is very fully guarded against by such anastomoses".

2 The Principal Players

2.1 Cells of the Vessel Wall

Newly formed vessels as well as those that remodel are comprised of several basic cell types, each of which has specific roles and functions in the development of the vasculature. Endothelial cells, which

line the inner surface of all blood vessels, have received the most attention with respect to their role in angiogenesis. These cells, which are normally quiescent and nondividing, can undergo a rapid phenotypic switch in response to growth factors and inflammatory stimuli. When activated, the endothelial cells upregulate adhesion molecules for inflammatory cells, secrete chemokines that recruit inflammatory cells and possibly stem cells to sites of activation, and secrete metalloproteinases and other proteases that play a role in the breakdown of the extracellular matrix and liberation of additional growth factors either bound to the matrix or present in latent forms. Following the degradation of the basement membrane, endothelial cells then develop sprouts from preexisting microvessels, invade the extracellular matrix, form tubes, and connect the tips of these tubes to create loops capable of handling blood.

Periendothelial cells are required for the final stages of vessel maturation. At the level of the capillary, this role is filled by pericytes, a perivascular cell with multifunctional activities. The pericytes extend long cytoplasmic processes over the surface of the endothelial cells. Endothelial cells and pericytes make interdigitating contacts and can also communicate through the formation of gap junctions. There are differences in pericyte morphology and the degree of coverage in different vascular beds. However, the pericytes appear to play an important role in protecting new endothelium-lined vessels against rupture or regression. In the developing retinal vasculature, for example, vessels regress more easily as long as they are not covered by pericytes, and in diabetes, the loss of pericytes around the retinal vasculature is associated with aneurysms, vasodilatation, and bleeding.

Vascular smooth muscle cells are highly specialized cells, which in mature arteries have the principal function of contraction and regulation of the blood vessel tone. Normally, these cells proliferate at a very low rate and exhibit a low synthetic activity. These cells express unique contractile proteins and ion channels. Highly specific signaling molecules coordinate the contractile functions of these cells. As new vessels form, vascular smooth muscle cells play a key role in the overall morphology. During this process, or when vessels remodel, vascular smooth muscle cells exhibit a high rate of proliferation and synthesize extracellular matrix molecules such as collagen, elastin, and proteoglycans.

The formation of larger vessels can occur by the enlargement of preexisting collaterals (discussed below), or possibly through the *de novo* growth of collateral vessels. There is some argument that so-called "*de novo*" collaterals may be an artifact of the resolution limits of angiography. Collateral vessels on angiograms are thought to be new vessels simply because they were not visible previously. However, there may not have been enough flow through collateral vessels for them to be filled with the contrast reagent, and thus the abundance of preexisting collateral vessels has likely been seriously underestimated. It is possible that newly formed capillaries could remodel into arterioles by recruiting smooth muscle cells. The most convincing evidence for the formation of *de novo* collateral vessels comes from observations in pigs and dogs where relatively large, angiographically visible collateral vessels develop in the connective tissue that forms around ameroid occluders (although these could still be enlarged *vasa vasorum* or small blood vessels ramifying on the outside of a major artery or vein).

2.2 Growth Factors and Their Receptors

2.2.1 VEGF Family

Vascular endothelial growth factor (VEGF; also called VEGF-A to distinguish it from other VEGF family members) is probably the best characterized and certainly the most ''popular'' (in terms of number of publications on the subject!) of the angiogenic growth factors.

The VEGF family members and their receptors are depicted in Fig. 2. There are three VEGF receptors (VEGFR-1 to VEGFR-3), which interact with the VEGF family members (VEGF-A through -E, as well as the related placental growth factor, PlGF). Each of the VEGFs has a characteristic receptor-binding pattern (Fig. 2).

Placental growth factor was originally discovered, as its name implies, in the placenta. However, PlGF is found in many tissues and is produced by many cell types including vascular smooth muscle cells, inflammatory cells, bone marrow cells, neurons, and tumor cells. Although quiescent endothelial cells release minimal amounts of PlGF, activation by angiogenic stimuli such as VEGF or HGF markedly upregulates PlGF. PlGF can be alternatively spliced, and to date, four different isoforms have been described which differ in size and their binding properties (PlGF-1 ($PlGF_{131}$), PlGF-2 ($PlGF_{153}$), PlGF-3 ($PlGF_{203}$), and PlGF-4 ($PlGF_{224}$)). PlGF-2 and -4 both contain an insertion of 21 amino acids at the carboxy terminus,

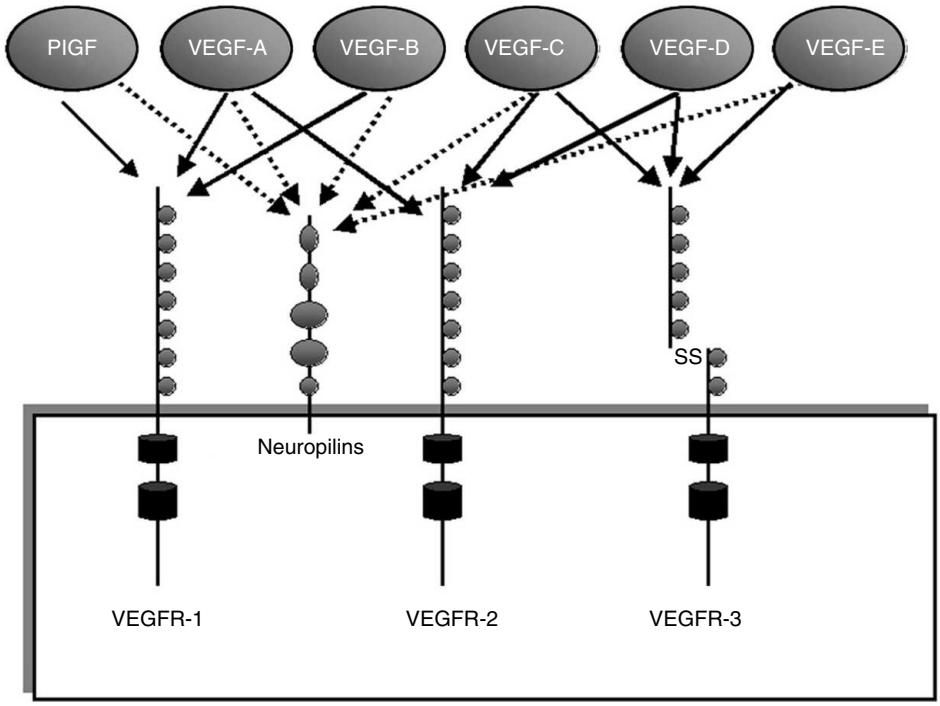

Fig. 2 Binding of the various VEGF family members to the VEGF tyrosine kinase receptors (VEGFR-1, VEGFR-2, and VEGFR-3) and the neuropilins.

which confers the ability to bind polyanionic substances such as heparan sulfate proteoglycans (HSPG) and also to the coreceptors neuropilin 1 and 2. PlGF-1 shares 53% amino acid identity with the PDGF-like region in VEGF, and an overall identity of 42%. However, the recent elucidation of the crystal structure of PlGF showed that the overall structure of human PlGF-1 is remarkably similar to VEGF-A. The physiological roles of PlGF are still unclear, but it may synergize with VEGF-A by forming heterodimers or by potentiating VEGF signaling. PlGF likely elicits responses in cells and tissues that express VEGF-R1 (e.g. smooth muscle cells, monocytes, possibly vascular, and hematopoietic stem cells/progenitors from the bone marrow). PlGF null mice appear to have normal embryonic development but aberrant responses in models of pathological angiogenesis.

VEGF-B shares about 43% amino acid sequence identity with $VEGF_{164}$. VEGF-B binds VEGFR-1 and neuropilins. VEGF-B is also alternatively spliced ($VEGF\text{-}B_{167}$ and $VEGF\text{-}B_{186}$) resulting in a frame shift and two nonhomologous C-termini. In contrast to other VEGF family members, VEGF-B does not contain any N-linked carbohydrates. The shorter isoform of VEGF-B, $VEGF\text{-}B_{167}$, is not glycosylated at all whereas the longer form, $VEGF\text{-}B_{186}$, is O-glycosylated. The function of VEGF-B is really not well characterized. Mice deficient in VEGF-B have a mild cardiac phenotype (defects in atrial conduction, smaller hearts, dysfunctional coronary vasculature, and impaired recovery from cardiac ischemia). VEGF-B has a wide tissue distribution abundant in heart, skeletal muscle, and brown fat. The predominant isoform seems to be $VEGF\text{-}B_{167}$.

VEGF-C and VEGF-D have less homology to VEGF-A, but are mitogenic for vascular endothelial cells *in vitro* (although less potent) and stimulate angiogenesis *in vivo*. VEGF-C and VEGF-D bind VEGFR-2 and VEGFR-3 as well as neuropilins. Interestingly, the expression of VEGFR-3 becomes highly restricted to lymphatic endothelial cells during embryogenesis. VEGF-C and VEGF-D specifically stimulate the proliferation of lymphatic endothelial cells, whereas VEGF-A does not induce any changes in the lymphatic vasculature. Mice deficient in VEGFR-3 die at E9.5 of cardiovascular failure as a result of an impairment in the remodeling and maturation of large vessels. VEGF-C and VEGF-D have long N- and C-terminal extensions that flank the VEGF-homology domain. VEGF-C is synthesized as a precursor protein that undergoes proteolytic processing. The C-terminal domain is cleaved upon secretion, but remains associated with the N-terminal domain by disulfide bonds, thus giving rise to a disulfide-linked tetramer composed of 29-kDa and 31-kDa polypeptides. Upon processing of the N-terminal propeptide, the ''mature'' form is released, which consists of two 21-kDa polypeptide chains. These polypeptide chains correspond to the VEGF homology domain. Incomplete or additional proteolytic processing can also lead to two other fragments that migrate on reducing SDS-PAGE gels with apparent MW of 15 and 43 kDa. The full-length and so-called ''mature'' form of VEGF-C will bind to VEGFR-3 with high affinity but high-affinity interactions with VEGFR-2 require proteolytic processing.

The functions of VEGF-A have been extensively characterized and new roles continue to be unveiled. VEGF-A binds to VEGFR-1 and VEGFR-2, as well as to neuropilins 1 and 2. It appears that VEGFR-2 mediates the biological effects of VEGF-A on endothelial cells, whereas VEGFR-1

probably functions as a decoy receptor (discussed below). VEGF-A has the distinction of being one of the few molecules where even the deletion of one allele (e.g. VEGF-A −/+ mice) is embryonically lethal, underscoring the critical importance of this growth factor to vascular development. The biological activities of VEGF-A are primarily restricted to the vascular endothelium, which selectively expresses VEGFR-2. Biological effects of VEGF-A on endothelial cells include stimulation of proliferation, migration, increased vascular permeability, and promotion of survival. However, VEGF-A also can elicit responses in VEGFR-1, expressing cells such as monocytes, smooth muscle cells, dendritic cells, and osteoclasts.

VEGF-A is differentially spliced from eight exons, resulting in a number of different isoforms that are named by their amino acid number: $VEGF_{206}$, $VEGF_{189}$, $VEGF_{183}$, $VEGF_{165}$, $VEGF_{145}$, and $VEGF_{121}$ (Fig. 3). These isoforms vary in their patterns of expression and their binding properties for heparan sulfate proteoglycans, and the coreceptors, neuropilin 1 and 2. For example, $VEGF_{121}$ binds neither HSPG nor the neuropilins unlike $VEGF_{145}$ and $VEGF_{165}$. It is thought that the differences in the interactions with neuropilins and heparan sulfate proteoglycans contribute to the differences in potency of the different isoforms.

Recently, a new series of VEGF isoforms that contain an alternative COOH terminus has been described. In these alternative isoforms, instead of the first 18 nucleotides of exon 8, a more distal splice site is used, resulting in a novel

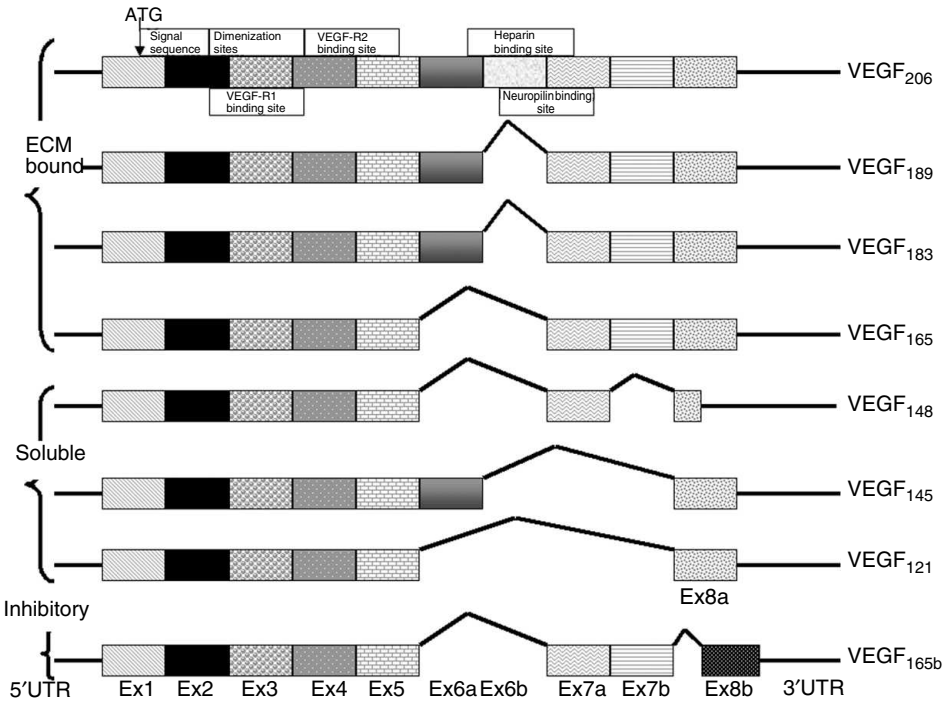

Fig. 3 Alternative splice variants of VEGF-A generating different VEGF-A isoforms.

COOH terminus. These new splice variants have a number of interesting features. Since they contain normal exons 1–5, the isoforms are likely to bind receptors, be secreted and dimerize. However, Keyt and coworkers demonstrated that it was the COOH-terminal of VEGF that conferred biological activity. Thus far, the alternative (so-called "b") isoforms of VEGF have none of the inherent biological activities of VEGF-A (e.g. proliferation, migration) and, moreover, appear to have potent inhibitory actions on VEGF-A mediated activities, presumably by either competing with the receptors or by forming inactive heterodimers. Since the commercial antibodies, cDNA probes, and RT-PCR reagents available against VEGF-A do not differentiate the active from the "b" isoforms, it raises some interesting issues with regard to the apparent levels of VEGF-A in normal and pathological specimens.

The VEGFR are glycosylated, type-I integral membrane proteins with seven immunoglobulin-like domains forming the extracellular portion and a split tyrosine kinase domain forming the interior portion. The VEGFR are closely related to the PDGF receptors (see below). VEGFR-1 (also known as *flt*-1) has the highest affinity for VEGF, but as discussed above, in endothelial cells at least, appears to function as a decoy receptor. VEGFR-2 (also known as *kdr*) is selectively expressed on endothelial and hematopoietic precursor cells, and mediates all of the known activities of VEGF-A on vascular endothelium.

The neuropilins (NRP) were first described as neuronal receptors for axon guidance factors for members of the semaphorin family. It was later found, however, that the neuropilins were expressed on endothelial cells and were also able to function as receptors for some forms of VEGF-A ($VEGF_{165}$ binds both NRP1 and NRP2; $VEGF_{145}$ binds NRP2 but not NRP1; $VEGF_{121}$ does not bind either). Other VEGF family members such as PlGF2 and VEGF-B bind to NRP1 and PlGF-2 and VEGF-C bind to NRP2. The neuropilins have short intracellular domains that apparently do not transduce signals subsequent to either semaphorin or VEGF binding. It is thought that the neuropilins form complexes with the VEGFR, facilitating signal transduction.

Potential beneficial effects of VEGF-A in therapeutic angiogenesis were first suggested by experiments in which supplemental VEGF, administered either as a recombinant protein or as naked DNA, augmented collateral blood flow in a number of species with experimentally induced hind limb or myocardial ischemia. A recent study by Rissanen and coworkers compared the activities of different VEGF family members in a rabbit hind-limb model. In these studies, the effects of administering adenoviral vectors expressing VEGF-A, VEGF-B, VEGF-C, and VEGF-D, as well as a VEGFR-3 specific mutant ($VEGF\text{-}C^{156S}$) were compared. The authors also explored the effects of adenoviruses expressing either full-length or proteolytically processed VEGF-D ($VEGF\text{-}D^{\Delta N\Delta C}$). They found that VEGF-A and $VEGF\text{-}D^{\Delta N\Delta C}$ induced the strongest angiogenic and vascular permeability effects. Full-length VEGF-C and VEGF-D induced predominantly lymphangiogenesis and the VEGFR-3 specific ligand $VEGF\text{-}C^{156S}$ exclusively promoted lymphangiogenesis. Interestingly, VEGF-B did not promote either angiogenesis or lymphangiogenesis. The lack of effect of VEGF-B suggested that VEGFR-1 signaling alone might not be capable of initiating angiogenesis. However, collateral formation/arteriogenesis is impaired in PlGF−/− mice and this phenotype is rescued when the PlGF−/−

mice are treated with a local administration of PlGF. PlGF and VEGFR-1 are upregulated in postischemic collateral vessels. Moreover, local infusion of PlGF in the rabbit hind-limb model of arteriogenesis potently induces collateral growth, an effect that is abolished by monocyte depletion. It is currently thought that the role of PlGF/VEGFR-1 may be to recruit monocytes (which express VEGFR-1). The apparent discrepancies between the effects of PlGF and VEGF-B remain confusing, although they might result from differences in the methodology as well as species.

2.2.2 **FGF Family**

The FGFs comprise a large family of 23 related peptide growth factors (FGF-1 to FGF-23), although four of them (FGF-11–14) are probably not canonical FGFs. FGFs modulate the proliferation and differentiation of many different cell types of both mesenchymal and neuroectoderm origins. Increased FGF signaling, due to mutations in either the FGFs or their receptors, leads to a variety of human skeletal disorders, including dwarfism and craniosynostosis syndromes. Most of the FGFs (FGF-3–8, -10, -15, -17–19 and -21–23) have N-terminal signal peptides and are readily secreted. In spite of the lack of an obvious signal sequence, FGFs-9, -16, and -20 are also secreted. FGF-1 and FGF-2 also lack a signal sequence and are apparently not secreted, but can be found on the cell surface and deposited within the extracellular matrix. FGF-9 has a noncleaved amino-terminal hydrophobic sequence that is required for secretion; a third set of the FGFs (FGF-11-14) lack signal sequences and are believed to remain inside the cell. In the adult, FGFs are thought to be involved in the processes of both physiological (e.g. in response to exercise, wound healing) and pathological (e.g. tumors, retinopathies) angiogenesis. With respect to therapeutic angiogenesis, the role/effects of two of the FGF family members (FGF-2 and FGF-4) have been evaluated.

FGF-1 and FGF-2 were the first FGF family members to be isolated and were originally named acidic and basic FGF respectively on the basis of their isoelectric points. However, FGF-1 and FGF-2 differ from most other FGFs in several important ways. FGF-1 is unique among FGFs in that it binds with high affinity to all of the known receptor isoforms. Both FGF-1 and FGF-2 are found in the cytosol and lack a signal peptide at their 5′ ends. Despite the lack of a signal peptide, both factors seem to be released from cells through a nonclassical secretory pathway. Both FGF-1 and FGF-2 have also been found in the cell nucleus and a putative nuclear localization signal has been identified at the 5′ end of the FGF-1 protein. There are also higher molecular weight forms of FGF-2, which derive from alternative translation initiation sites in the 5′ region of the *FGF2* gene. These isoforms localize to the nucleus. The precise function(s) of these nuclear forms of FGF-1 and FGF-2 remains unclear.

FGF-2 is a potent regulator of many cellular functions and phenomena, including cell proliferation, differentiation, survival, adhesion, migration, motility and apoptosis, and processes such as limb formation, wound healing, tumorigenesis, angiogenesis, vasculogenesis, and blood vessel remodeling. FGF-2 is a potent mitogen and chemotactic factor for endothelial cells and also stimulates smooth muscle cells and pericytes to proliferate. Other processes relevant to angiogenesis that are regulated by FGF include stimulation of plasminogen activator production and matrix metalloproteinase (MMPs) expression.

The latter two responses play an important role in vessel destabilization and breakdown of the extracellular matrix, a process required for endothelial cell sprouting and invasion. However, despite these activities, the deletion of the FGF-2 gene resulted in a phenotype with only mild cardiovascular, skeletal, and neuronal abnormalities.

FGF-4 has the distinction of being one of the minorities of the FGF family members whose deletion results in embryonic lethality (FGF-8, -9, -10, -15, and -18 are also embryonic lethal or lethal at P0). FGF-4 is absolutely required for preimplantation mouse development apparently due to a requirement for FGF-4 to maintain trophoectoderm and primitive endoderm identity at embryonic day 4.5. With respect to angiogenesis, it is not really clear whether FGF-4 plays a role in endogenous angiogenic responses. *In vitro* studies suggest that it acts in a manner similar to FGF-2, although somewhat weaker in terms of endothelial cell proliferation. Nonetheless, adenoviral gene delivery studies have now shown that delivery of FGF-4 by this means promotes neovascularization in animal models and has promising effects in the clinic.

A family of four receptor tyrosine kinases mediates the diverse effects of the FGFs. These receptors are characterized by an extracellular ligand-binding region consisting of three immunoglobulin-like (Ig) domains (D1 to D3), a single transmembrane helix, and a cytoplasmic portion with the protein tyrosine kinase activity. Alternative mRNA splicing leads to additional isoforms of these receptors and thereby alters ligand binding. One such splicing event results in the skipping of exons encoding D1, resulting in a shorter, two Ig-like domain form of the receptor. Binding specificity for the different FGF family members resides in the D2 and D3 Ig domains as well as a short linker between D2 and D3. It has been suggested that the short form of the receptor may have a higher affinity for some FGFs than the long form. Another alternative splicing site specifies the sequence of the carboxy-terminal half of D3, resulting in either the 3b (IIIb) or 3c (IIIc) isoform of the FGF-R. These splicing events are thought to be regulated in a tissue-specific manner, with exon IIIB more prevalent in cells of epithelial lineage, and IIIc in cells of mesenchymal origin.

As is the case for many of the receptor tyrosine kinases, receptor dimerization is required for FGF signaling. FGF signaling also requires heparin or HSPG. Interaction with HSPG or heparin stabilizes FGFs to thermal denaturation and proteolysis and, moreover, can restrict the diffusion distance from the site of FGF production.

There are now many published studies with different animal models that support the concept that administration of FGF-2 as protein, naked DNA, or as an adenoviral gene-therapy vector can promote angiogenesis, improve myocardial perfusion, improve endothelial vasodilatory function, and promote the development of collateral vessels. Gene therapy using adenovirus serotype 5, in which the E1A and E1B genes have been replaced by the human FGF-4 gene driven by a constitutive cytomegalovirus promoter (Ad5FGF-4), was effective in stimulating collateral vessels in a porcine model of stress-induced myocardial ischemia and in a rabbit hind-limb ischemia model.

2.2.3 PDGF Family

The platelet-derived growth factor family is comprised of four polypeptides, PDGFA, B, C, and D, which occur in the form of homodimers (PDGF-AA, PDGF-BB, PDGF-CC, PDGF-DD) or heterodimers

(PDGF-AB). To date, there are two known PDGF receptors, an α-receptor (PDGFR-α) and a β-receptor (PDGFR-β). The PDGFR-α receptor will bind all forms of PDGFs except PDGF-DD, while the PDGFR-β receptor binds all forms of PDGFs except PDGF-AA. When a dimerized PDGF molecule binds one of the above receptor molecules, receptor dimerization occurs, followed by activation of the receptor tyrosine kinase activity, leading to the autophosphorylation of the cytoplasmic domain of the receptor.

PDGF was originally purified from platelets (as implied by its name), but it was subsequently found to be made by many other cell types including fibroblasts, keratinocytes, myoblasts, epithelial cells, and macrophages. Endothelial cells derived from the microvasculature express PDGFR-β and the addition of PDGF-BB to microvascular endothelial cells stimulates DNA synthesis and tube formation in *in vitro* assays. Importantly, PDGF also stimulates the proliferation of smooth muscle cells and pericytes. The critical role for PDGF in the maturation of new blood vessels was demonstrated in genetic mouse models. Mice deficient in either PDGF-B or PDGFR-β develop grossly normal blood vessels, but die *in utero* from hemorrhage and edema. The cerebral microvasculature of these mice was the major site of hemorrhage and leakiness; in these vessels pericytes were absent and the vessel lumens were dilated. In other organs, pericytes may have been present (it is difficult to distinguish pericytes from smooth muscles because of a paucity of specific markers) but dysfunctional. It is thought that PDGF therefore plays a role in the recruitment and the maturation of pericytes and thus plays an important role in the stabilization of newly formed blood vessels.

Cao and coworkers studied the angiogenic synergy, vascular stability, and improvement of hind-limb ischemia using combinations of PDGF-BB, VEGF-A, and FGF-2. In this study, the authors employed *in vivo* angiogenesis assays (mouse corneal micropocket assay and mouse matrigel assay). PDGF-AB and PDGF-BB induced robust angiogenesis in the cornea, whereas the vessel areas induced by PDGF-AA were significantly smaller. To test the possibility that PDGF-BB might modulate FGF-2 or VEGF-A-induced angiogenesis, these growth factors were implanted alone or in combination into mouse corneas. FGF-2 and VEGF-A alone induced intense corneal neovascularization and marked synergy was observed in corneas coimplanted with PDGF-BB and FGF-2. The vessel areas were significantly greater and the newly formed blood vessels appeared better organized than those elicited by FGF-2 alone. In contrast, PDGF-BB did not improve the quality of the VEGF-induced vascular networks. Similar results were observed in the matrigel model. To evaluate vessel stability, these authors monitored the mouse corneal networks for more than 210 days. The newly formed vessels in corneas treated with PDGF-BB alone regressed after 24 days. FGF-2-induced vessels remained stable for up to 40 days, but had almost all regressed by 70 days. In contrast, corneas implanted with the combination of PDGF-BB and FGF-2 developed vascular networks that remained stable for over 210 days. PDGF-BB did not improve the longevity of VEGF-A induced vessels, which were barely detectable after ~70 days. The combination of VEGF-A and FGF-2 produced an additive effect on vascular network development and the vessels developed also remained for a somewhat longer period (~100 days). To evaluate the possible role of mural cells in

the longevity of vessels induced by PDGF-BB and FGF-2, the authors performed a histological analysis of the vessels, staining for endothelial markers (CD31) and pericyte/smooth muscle markers (desmin). The vessels induced by the combination of PDGF-BB and FGF-2 had a significantly greater smooth muscle/pericyte coating than the FGF-2 alone group. These authors also examined the synergistic interactions of FGF-2 and PDGF-BB in the rat hind-limb ischemia model. Angiographic analysis was performed 23 days after ligation of the femoral artery. In agreement with earlier studies, FGF-2 alone increased the number of collateral vessels. Delivery of PDGF-BB alone was only moderately effective in improving collateral vessel formation. The combination of FGF-2 and PDGF-BB potently stimulated collateral growth with a higher density of collateral vessels. The high numbers of collaterals induced by the combination of PDGF-BB and FGF-2 were maintained for more than 60 days without regression. The effects on collaterals also correlated well with hind-limb perfusion scores. These observations clearly suggest that the combination of FGF-2 and PDGF-BB can interact synergistically to induce angiogenesis, arteriogenesis, and long-lasting functional vessels. Recent studies by Hao and coworkers also suggest that the combination of FGF-2 and PDGF-BB (administered by dual gene transfer) also resulted in an increased number of capillaries and arterioles and more stable vessels in a rat model of myocardial infarction.

2.2.4 TGF-β Family

Transforming growth factor-βs are actually a superfamily of more than 35 members, including the TGF-βs, BMPs (bone morphogenic proteins), GDFs (growth differentiation factors), activins, inhibins, MIS (Müllerian inhibiting substance), nodal, and leftys. The best-known member is TGF-β1. TGF-β1 is secreted as a latent form where the activity of the mature domain is masked by the propeptide LAP (latency associated peptide). This biologically inactive precursor must be activated by proteases such as plasmin or cathepsin D. It can also be activated by low pH, chaotropic agents such as urea, and by heating. Many different cells, both normal and transformed, express TGF-β1 and like FGF2, TGF-β1 binds to and is found in the extracellular matrix of many tissues. Endothelial cells, pericytes, and smooth muscle cells all express TGF-β receptors, and thus TGF-β can exert many effects on the vasculature. TGF-β significantly inhibits the proliferation and migration of endothelial cells (although low doses may stimulate growth), and also may stimulate (low dose) or inhibit (higher doses) endothelial tube formation. The effects of TGF-β on tube formation may be mediated by the ability of TGF-β to modulate urokinase and plasminogen activator inhibitor levels and to stimulate the production of protease inhibitors such as tissue inhibitor of metalloproteinase. TGF-β is also a potent stimulant of extracellular matrix production.

The ligands of the TGF-β superfamily signal through a family of transmembrane serine/threonine receptor kinases. There are two subfamilies of TGF-β receptors known as the Type I and Type II receptors. Upon ligand binding, these receptors interact. The type I receptors have a somewhat confusing nomenclature due to their simultaneous discovery by different groups. However, a common name applied to many of them is ALK receptors (activin receptor-like kinases). TGF-β1 binds directly to the type II receptors, then

recruits type I receptors, and once an active ligand-type I/type II receptor complex is formed, the type II receptors activate type I receptors by phosphorylation. The type I receptors subsequently phosphorylate downstream SMAD proteins that propagate the signal from the cytoplasm to the nucleus.

A third distinct type of cellular receptors for the TGF-β ligands are the type III receptors, exemplified by betaglycan and endoglin. Endoglin is expressed at high levels in endothelial cells, and at lower levels in monocytes, erythroid precursors, and other cell types.

TGF-β1 can stimulate angiogenesis *in vivo*, an activity that may result from the proinflammatory effects of the protein TGF-β1, which is chemotactic for monocytes and fibroblasts.

Genetic studies have strongly suggested important roles for TGF-β1 in the development of the vasculature. Mice lacking TGF-β1 exhibit two phenotypes. About 50% of the mice die *in utero* as a result of defects in the yolk sac vasculature and hematopoietic system. The other embryos survive (possibly through maternal transfer of TGF-β1), but die at 3 to 4 weeks of age as a result of severe multifocal inflammation. Mice deficient in TGF-β receptor 1 (also known as ALK-5 or TβRI) also die midgestation as a result of severe defects in the vascular development of the yolk sac and placenta and an absence of circulating red cells. In the vascular system, there is an additional type I receptor for TGF-β1, ALK-1. ALK-1 deficient mice die around midgestation, also exhibiting severe vascular abnormalities. Targeted disruption of the murine endoglin (Eng) gene is also embryonically lethal at E11.5 due to defects in vascular development. Eng-null mutants exhibit both poor vascular smooth muscle cell development and arrested endothelial remodeling. Endoglin thus appears to be essential for the differential growth and sprouting of endothelial tubes and the recruitment and differentiation of mesenchymal cells into vascular smooth muscle cells and pericytes.

Van Royen and coworkers evaluated the activity of exogenous application of TGF-β1 in a model of arteriogenesis in the rabbit hind limb. TGF-β1 was delivered locally (0.48 $\mu g\ kg^{-1}\ d^{-1}$) into the collateral circulation via an osmotic minipump. Compared to Phosphate Buffered Saline (PBS)-treated controls, TGF-β1-treated animals had an increased number of visible collateral arteries as well as the conductance of the collateral circulation. The authors attributed at least part of the arteriogenic response to monocyte activation by TGF-β1. Isolated human monocytes treated with TGF-β1 exhibit an upregulation of the MAC-1 receptor as well as increased monocyte adhesion and transmigration across endothelial monolayers.

2.2.5 HGF

Hepatocyte growth factor (HGF; also known as scatter factor) is a mesenchyme-derived factor with multiple activities including the regulation of cell growth, motility, and morphogenesis of various cell types including epithelial and endothelial cells. HGF is a large, multidomain protein that is structurally similar to plasminogen. HGF has six domains – an amino-terminal domain, four Kringle domains, and a serine proteinase homology domain. The serine proteinase homology domain lacks enzymatic activity. HGF is synthesized as a large, single-chain inactive precursor (pro-HGF), which is converted proteolytically into a two-chain, active heterodimer. HGF also binds to heparan sulfate proteoglycans with high affinity, although HSPG binding is not essential for receptor activation. The

receptor for HGF was identified as c-*met*, a proto-oncogene.

Met is a disulfide-linked heterodimer, consisting of an extracellular α-chain and a longer β-chain. The β-chain consists of an ectodomain, the transmembrane helix, and the cytoplasmic portion, which contains kinase domains. Met has a unique bidentate docking site, which comprises two tyrosine residues (Y1349 and Y1356) and the surrounding amino acid residues. When phosphorylated, this docking site binds substrates such as Gab1, Grb2, and phosphatidylinositol 3-kinase. Although deletion of HGF or met (both of which were embryonically lethal) demonstrated an essential role of this signaling system in development, the phenotype was not overtly vascular. The livers of both the HGF−/− and met−/− mice were considerably reduced in size because of the decreased proliferation and increased apoptosis of the hepatocytes. The mice also demonstrated a placental defect and a reduced survival of sensory neurons and a complete absence of all muscle groups, which derive from migrating precursor cells.

In the adult, HGF and met are broadly expressed and have been implicated in responses to injury, liver regeneration, tumor growth and metastasis, and angiogenesis. HGF is a potent endothelial mitogen, motogen, and morphogen. Moreover, several *in vivo* studies have shown that this growth factor is a potent inducer of angiogenesis.

The role of HGF in arteriogenesis has not been extensively studied. However, HGF is induced in the skeletal muscle of both rats and mice following ischemic injury. HGF has also been implicated in the regeneration of capillary endothelial cells in ischemically injured myocardium. Van Belle and coworkers examined the effects of VEGF-A and HGF, alone and in combination, on endothelial proliferation and migration *in vitro*. They also compared the effects of VEGF-A and HGF on capillary density and collateral development in the rabbit hind-limb ischemia model. These authors found that the combination of VEGF-A and HGF synergistically induced endothelial proliferation and migration *in vitro*. In the rabbit hind-limb ischemia model, HGF appeared to produce a superior response in terms of capillary density and collateral formation compared to either VEGF or vehicle. The combination of HGF and VEGF also acts synergistically in *in vitro* assays of endothelial tube formation, and a recent gene expression profiling study demonstrated that these two growth factors elicit different profiles of gene expression and when combined, exhibit considerable synergy in both the magnitude and numbers of new genes upregulated. Several additional studies have provided substantial evidence that HGF, administered as a recombinant protein or as naked DNA or as an adenoviral vector, is a potent inducer of arteriogenesis. However, combination studies of the HGF with VEGF, TGF-β1, or PDGF-BB in arteriogenesis models have not been reported to date.

2.2.6 **Angiopoietins**

The angiopoietins (Ang) are a family of secreted proteins, four of which have been identified to date, that bind to Tie family receptor tyrosine kinases. Two Tie receptors have been identified thus far, Tie1 and Tie2 (Tek); interestingly the distribution of these receptors appears to be selective for the vascular endothelium and some cells of the hematopoietic cell lineage. An important role for these molecules was first revealed by gene knock-out studies. Ang1

and Tie2 deficient mice have similar embryonic lethal phenotypes, characterized by severe defects in vascular remodeling, reduced numbers of endothelial cells, insufficient vessel stabilization, and deferred vessel maturation. Application of the Ang1 protein or expression in transgenic mice can also counteract some of the side effects of VEGF such as increased vessel leakiness, while having an additive effect on the angiogenic effects of VEGF. Tie1-deficient mice develop extensive edema and hemorrhage and die either perinatally or at embryonic day 14.5. A ligand for Tie1 has not been identified. Ang-2 was first characterized as a related protein to Ang1 that could bind Tie2 and antagonize Ang1. Overexpression of Ang2 during development leads to phenotypes very similar to those observed in Ang1-deficient animals. It is thought that Ang2 may induce vessel destabilization and allow angiogenic sprouts to form and respond to other growth factors. Ang1 mRNA is predominantly expressed in cells surrounding the endothelium such as the smooth muscle cells, whereas in the adult, Ang2 is selectively expressed in endothelial cells at sites of vascular remodeling (e.g. ovary, uterus, placenta). Ang2 expression also appears to be regulated by hypoxia.

Siddiqui and coworkers examined the effects of Ang1 and VEGF-A_{165} gene therapy (alone and in combination) in a mouse model of myocardial ischemia. In the ischemic myocardium, administration of either plasmid resulted in an increase in the ratio of arterioles to capillaries; dual administration seemed to further increase the number of arterioles. These observations suggest that evaluation of the combinations of Ang1 with VEGF or other growth factors might be a fruitful area for further investigation.

2.3 Inflammation

Inflammation promotes angiogenesis in several different ways. Sites of inflammation are often also hypoxic, and as discussed above, hypoxia upregulates VEGF-A and Ang1. The plasma proteins that extravasate at sites of inflammation contain fibrinogen products and other protein fragments that can stimulate new vessel formation. Importantly, many of the cells recruited to the site of inflammation (macrophages, lymphocytes, mast cells, platelets, neutrophils) release angiogenic factors and enzymes that can further amplify an angiogenic response. These angiogenic factors include growth factors, cytokines, and proteinases like metalloproteinases.

There is increasing evidence that recruitment of monocytes may be a functionally important aspect of arteriogenesis. Monocytes have been identified on the endothelial lining of growing canine coronary collaterals; these cells are probably attracted by the endothelial expression of MCP-1, a monocyte chemoattractant. Local infusion of MCP-1 has been shown to improve collateral vessel formation in several studies. Fluid shear stress is a potent inducer of MCP-1 as well as of ICAM-1, an adhesion molecule to which the Mac-1 receptor of monocytes binds. Targeted disruption of the MCP1 receptor (CCR-2) in mice decreases collateral growth after femoral artery occlusion. Additionally, the weak arteriogenic effects of VEGF infusion may be due to the monocyte chemoattractant activity of VEGF for monocytes, which express VEGFR-1. This may also account for the reduced collateral artery growth observed in PlGF−/− mice (PlGF is selective for VEGFR-1).

An overlooked cell type in arteriogenesis may be the mast cell. Mast cells aggregate in the adventitia of growing collaterals and remain there for up to six weeks. Since these cells can secrete bFGF, VEGF, other vasoactive autocoids, platelet activating factors, and a variety of other cytokines, they may well play a paracrine role in the development or remodeling of collateral vessels.

2.4 Circulating Endothelial Precursors/Bone Marrow-derived Cells

Bone marrow provides a rich reservoir of stem and progenitor cells. Recently, a rare population of cells called ''endothelial progenitor cells'' (EPCs) has been described. The ''EPCs'' can be mobilized to the circulation, and are thought to contribute to the formation of new vessels. There is also a population of circulating endothelial precursors (CEPs). CEPs are thought to originate from EPCs in the bone marrow, and may also be recruited from the parenchyma of the systemic vasculature. These cells are defined by a number of phenotypic markers (see Table 2).

Angiogenic factors and chemokines are thought to recruit subsets of proangiogenic hematopoietic cells, which along with EPCs and CEPs may contribute to new blood vessel formation. There are numerous studies which now suggest that bone marrow-derived cells are recruited to areas of neoangiogenesis following wound healing, limb ischemia, post myocardial infarction, endothelialization of vascular grafts, retinal and lymphoid organ neovascularization, and angiogenesis associated with neonatal development and tumor growth. Vigorous exercise has also been shown to increase the number of CEPs in peripheral blood.

Several studies have shown that transplantation of a bone marrow-derived stem or EPCs seems to improve recovery of perfusion and function in animal models of myocardial and peripheral ischemia. The relative contribution of these transplanted cells to the endothelium of growing vessels varies considerably from one study to another, ranging from 0% to $\geq$50%, although

Tab. 2 Markers for endothelial precursor cells (EPCs), circulating endothelial precursors (CEPs), and circulating endothelial cells (CECs).

Cell type	*Origin*	*Specific phenotypic markers*
EPCs	Bone marrow, vascular parenchyma, umbilical cord blood	CD133(AC133)+, VE-cadherin, VEGFR-2+, CD34+, CD31+, VEGFR-1+, CD146+, CXCR4+, Di-Ac-LDL uptake, vWF+, E-selectin, Ulex europeas binding
CEPs	Peripheral blood	CD133+, VEGFR2+, VE-cadherin, CD34+, CD31+, VEGFR-1+, CD146+, CXCR4+, Di-Ac-LDL uptake, vWF+, E-selectin, Ulex europeas binding
CECs	Endothelial lining of vessel wall	CD133NEG, VEGFR-2+, CD146+, VE-cadherin+, CD34+, CD31+, Di-Ac-LDL uptake, vWF+, E-selectin, Ulex europeas binding

in most studies this figure denotes that 50% or more of the capillaries examined have at least one single transplanted cell. It is important to emphasize the results of recent studies employing laser confocal image analysis, which suggest that the so-called EPCs do not really incorporate into the vessel wall *per se*, but are closely associated with the vessel wall. The bone marrow-derived stem cells may thus play an important paracrine role, releasing cytokines or other growth factors.

2.5 Mechanical Factors

At present, relatively little is known about the endogenous signals for collateral artery growth. However, many investigators believe that the mechanical effects of increased blood flow play an important role. Prior to the occlusion of an artery or the formation of a hemodynamically significant stenosis, there is likely to be little flow across preexisting collateral arterial connections. However, with the narrowing or occlusion of a major artery, the distal arterial pressure falls, increasing the pressure gradient along preexisting collaterals, resulting in the establishment of unidirectional blood flow and an increase in flow in the midsection of the collateral vessels. In contrast to the distal site (which may be hypoxic), the region of the collateral artery is exposed to fully oxygenated blood. Physiologists have studied the effects of blood flow on arterial diameters using models of arteriovenous fistulas. Normally, blood flows from arteries into capillaries and then into the veins. When an arteriovenous fistula is present, blood flows directly from an artery into a vein, bypassing the capillaries. The increased flow in the artery results in arterial expansion. Wall shear stress (τ) can be calculated using the equation:

$$\tau = \frac{4\eta Q}{\pi a^3} \qquad (1)$$

where η = viscosity, Q = flow rate, and a = internal radius of the vessel. Therefore, an increase in flow will directly translate into an increase in shear stress and the expansion of the internal diameter (either mechanically, by relaxation of the vessel, or by active remodeling of the vessel) subsequently antagonizes this effect. There are other stresses on the vessel wall that may also be triggers for arterial remodeling, including the intraluminal pressure, which in turn creates circumferential, longitudinal, and radial stresses on the wall.

The vascular endothelium plays a critical role in the responses of the vessel wall to biomechanical stresses. Changes in wall shear stress can induce the expression of adhesion molecules such as ICAM-1 and VCAM-1, as well as the expression of chemokines (MCP-1) and matrix metalloproteinases. Mechanical strain may also induce MMP expression by vascular smooth muscle cells and monocyte/macrophages.

2.6 Hypoxia

It is important to emphasize that with regard to oxygen tension, arteriogenesis and angiogenesis differ fundamentally. Angiogenesis occurs in regions of hypoxia, which are usually quite distant from the site of collaterals that form to bridge a major arterial occlusion. Arteriogenesis, on the other hand, may occur in a normoxic environment. In the heart, this distinction may not be as clear; the distance from ischemic tissue and collateral vessel growth is small. As discussed above, hypoxia upregulates the expression of the

transcription factor, HIF-1α, which in turn regulates the expression of VEGF, Ang1, and VEGFR-1.

2.7 Vascular Remodeling

Following the acute phase of arteriogenesis that is dominated by inflammatory events, a second phase ensues, which is the slow remodeling of the arterial structure after the final diameters are attained. This requires the formation of a new elastic lamina by smooth muscle cells, the rebuilding of the media, and formation of an intima. Associated with these events is the down-regulation of tissue inhibitor of matrix metalloproteinases (TIMPs and MMPs) and upregulation and expression of new MMPs that remodel the matrix. Some of the smooth muscle cells of the old media appear to undergo apoptosis, and are replaced by new smooth muscle cells with a more synthetic embryonic-like phenotype. With the thickening of the vessel wall, the intercellular connections and communications between the cells change, an event paralleled by an increase in the expression of connexin 37 (an early marker of arteriogenesis) in the smooth muscle cells. The final stages of collateral remodeling are often accompanied by an increase in vessel length and thereby vessel-tortuosity.

3 Animal Models of Therapeutic Angiogenesis

A number of different species have been used to study arteriogenesis, the most common being the dog, pig, rabbit, rat, and mouse. These species vary significantly in their vascular anatomy, and these differences should be considered in evaluating the data. Hind-limb ischemia models usually involve ligation or resection of a femoral artery. It should be noted that in some species, for example, rats, this surgery may cause little or no ischemia (probably because of the presence of collaterals which provide sufficient blood flow). In rabbits, after femoral artery ligation, no increase in the expression of VEGF or hypoxia-inducible genes (HIF-1α, lactate dehydrogenase A) was found. For the heart, a common model is to ligate a major coronary artery or to place an ameroid constrictor around a major artery (which slowly constricts, allowing development of collaterals without necessarily causing a myocardial infarction). In recent years, mice have become very attractive models owing to the availability of different strains and genetically modified (e.g. transgenic and knock-out) animals.

Investigators use a variety of techniques to evaluate vascular structures in these models, and each method has its advantages and disadvantages. Histology, a commonly used method to analyze capillary and arteriole density and dimensions, is often a relatively subjective two-dimensional approach to a three-dimensional problem. Moreover, the sections examined may or may not provide an accurate representation of vascularity through the entire sample. Laser Doppler perfusion imaging is widely used to assess hind-limb perfusion in mice and rats; however, this method provides no anatomic information and only measures superficial perfusion. Other methods include the injection of fluorescent or radiolabeled microspheres, which offers the ability to study, in a longitudinal manner, perfusion to tissues. However, in a small animal such as a mouse, the injection of microspheres into the left ventricle can be

challenging because of their small size. Estimates of vascular surface area can be obtained using a radiolabeled endothelial specific antibody technique. Other recent imaging approaches include magnetic resonance angiography, positron emission tomography (PET), and micro-computed tomography (micro-CT). Recent studies with micro-CT suggest that this method may provide the required resolution and sensitivity for accurate assessment of mouse models.

Evidence for differences in blood flow recovery (as measured by Laser Doppler imaging) and hemoglobin oxygen saturation (as assessed by noninvasive tissue oximetry) in the distal hind limbs after femoral artery occlusion in different inbred strains of mice has been reported, with C57BL/6 mice recovering faster and more completely than BALB/c mice. At least, part of this difference may be due to the presence of more or larger preexistent collaterals in C57BL/6 than in BALB/c mice. Murine, rabbit, rat, and porcine models have been used to evaluate the potential roles of growth factors, gene therapy, stem cells, and other treatment modalities for therapeutic ''angiogenesis.'' An important caveat for many of these studies is that they are generally performed in young, healthy animals. The clinical situation is much more complicated with the additional issues of age, obesity, atherosclerosis, and diabetes. Several studies have now shown that arteriogenesis/angiogenesis is often impaired in aged, atherosclerotic, hyperlipidemic, or diabetic animals and humans. However, relatively few studies have evaluated the efficacy of different protein, plasmid, or gene-based therapies in these models, which may more closely reflect the clinical situation.

4 Clinical Trials

As discussed above, there are now numerous preclinical studies in mice, rats, rabbits, dogs, and pigs that have shown the potential of various angiogenic growth factors to restore blood flow and function to ischemic tissues. Quite reasonably, therefore, a number of these approaches have been evaluated clinically. To date, however, the translation of this experience into clinical success has been disappointing and it is clear that this approach is ''not ready for prescription'' just yet. Early, open-label uncontrolled studies seemed to predict spectacular success, but the later, well-controlled studies were less encouraging. There have been several recent reviews of the clinical data from these studies.

4.1 Protein-based Trials

One of the first trials to test a recombinant protein employed a combination of intracoronary and intravenous infusions of VEGF-A_{165} (the VEGF in Ischemia for Vascular Angiogenesis (VIVA) trial) (see Table 3). The clinical endpoints were exercise tolerance, myocardial perfusion, angina symptoms, or functional class. Although there was no significant benefit at 60 days, there was a trend towards a benefit in the high-dose VEGF165 group at 120 days.

The FIRST trial (FGF Initiating Revascularization Trial) evaluated a single intracoronary FGF2 infusion. In this study, there were significant improvements in functional status and angina symptoms in the FGF2 group; however, there was no benefit compared with placebo in terms of exercise capacity or myocardial perfusion at 90 days. A more promising result was

Tab. 3 Clinical trials in angiogenesis. Protein-based therapies.

Trial	*Name*	*Growth factor and route of administration*	*Patient population [N]*	*Clinical endpoints*	*Results*
VIVA	VEGF in ischemia for vascular angiogenesis (Phase II)	Intracoronary and intravenous VEGF165 protein infusions	178	At 60 days Exercise tolerance Myocardial perfusion Angina symptoms Functional class	No significant benefit Trend in favor of high dose VEGF165 seen at 120 days
FIRST	FGF initiating revascularization Trial(Phase II)	Single intracoronary FGF2 infusion	337	At 90 days Functional status Symptom class Exercise tolerance Myocardial perfusion	Significant improvement in functional status and symptom class No benefit compared with placebo for exercise or myocardial perfusion
Hep-Alg	Phase I/II	Polymer released FGF2	Given at time of coronary bypass surgery24	At 90 days Myocardial perfusion Symptom status	Significant improvement Improvement still seen at three-year follow-up
TRAFFIC	Phase II	Double intra-arterial FGF2 infusion	Patients with peripheral vascular disease190	At 90 days Walking time	Improvement seen at 90 days. However, no differences among treated groups after 6 months

obtained in a very small ($n = 24$), but randomized trial of a slow release formulation of FGF2 implanted (at the time of coronary artery bypass surgery) into unrevascularized myocardium. In these patients, there was significant improvement in perfusion and symptom status after 90 days in the high FGF2 group that was still seen at the 3-year follow-up.

The (Therapeutic angiogenesis with recombinant fibroblast growth factor-2 for intermittent claudication) TRAFFIC trial was the first randomized trial in patients with peripheral vascular disease. Patients in the treatment arm of this trial received two (30 days apart) intra-arterial infusions of FGF2. Interestingly, at 90 days, the FGF2 patients had improved peak walking times, but this difference was not maintained after six months.

4.2 Gene Therapy-based Clinical Trials

Gene therapy has several potential advantages over protein-based therapy. Probably the most important is that gene transfer can allow prolonged, local exposure. This advantage may be offset if there is low efficiency of gene expression and also if there is an immune response to the protein or virally infected cells. Uncontrolled regulation of gene expression may also pose risks; for example, several animal model studies suggest that overexpression of VEGF can lead to the formation of hemangioma-like structures and severe edema.

Studies exploring the efficacy and safety of gene therapy for therapeutic arteriogenesis are appearing with greater frequency in the literature. Some of these approaches have entered clinical trials, and this information is summarized in Table 4. While these early studies look promising, the majority of studies have been open-label without placebo controls, and past experience with the protein-based trials has clearly shown that there is a significant placebo effect.

The angiogenic gene-therapy (AGENT) studies were the first randomized, double-blind, placebo-controlled trials of therapeutic angiogenesis by gene transfer for myocardial ischemia. In the AGENT1 trial, Ad5-FGF4 enrolled 79 patients between 1998 and 2000. The principal objectives of the trial were safety evaluation and dose identification for larger clinical trails. Efficacy was assessed by determining the change in total exercise time and the time of onset of angina from baseline to follow-up (at 4 and 12 weeks) using a symptom-limited exercise treadmill test. Ad5-FGF4 was administered via a cardiac catheter. Overall, the FGF-4 therapy using the adenoviral vector was well tolerated without significant safety concerns. Importantly, there was no detectable FGF4 protein outside of the heart, and the calculated first pass extraction across the coronary circulation was 87% of the injected dose. The exercise treadmill testing suggested a trend towards improvement in the FGF-4 treated group, although it was not statistically significant.

The AGENT-2 trial was a randomized, double-blind placebo-controlled trial. This study showed that Ad5-FGF4 was more effective than the placebo in reducing the reversible perfusion defect size in patients with stable angina. The Ad5-FGF4 group also had a higher percentage of symptom-free patients at 8 weeks. However, the pivotal AGENT-3/-4 trials were stopped early because an interim analysis showed that the efficacy endpoints were unlikely to be met. The reasons

Title	*Phase*	*Reagent*	*Method of delivery and [n]*
VEGF2	Phase I/II	VEGF2 plasmid	Intramyocardial injection(19)
KAT	Phase II	VEGF165 protein, plasmid or adenovirus	Injection with PTCA or stenting(103)
Euroinject one	Phase II	Plasmid-VEGFA165	Percutaneous intracardiac injection(74)
REVASC	Phase II	Adenovirus VEGFA121(CAD)	Intracardiac injection via thoracotomy67
VEGF-POAD	Phase II	Adenovirus-VEGFA165(PAD)	54
RAVE	Phase II	Adenovirus-VEGFA121	105
AGENT-1	Phase I	Adenovirus FGF4(CAD)	79 (19 placebo, 60 receiving AdFGF4)
AGENT-2	Phase II	Adenovirus FGF4(CAD)	52 A = 35, P = 17
AGENT-3	Phase III (US)	Adenovirus FGF4(CAD)	Single intracoronary administration 450 A = 300 P = 150
AGENT-4	Phase III (Multinational)	AdFGF4(CAD)	Single intracoronary administration 450 A = 300 P = 150
AMG0001	Phase II	HGF plasmid(PAD)	
Del 1	PhaseI/II	Del-1 (PAD)	Intramuscular injection
NV1FGF	Phase II	FGF1 plasmid (PAD)	
Biobypass	Phase II	CAD and PAD	
HIF-1a	Phase I	CAD and PAD	

for the failure are unclear since the results of the trial have not been published to date. Overall, however, the results from these and other gene-based therapy trials have demonstrated that these approaches, if well designed, are safe and may still hold the promise of future success.

At this juncture, scientists and clinicians need to reevaluate the critical issues revealed by these studies in order to progress. Clearly, there is a need to better understand the biology of compensatory vascular growth before rushing into the next clinical trial.

5 Going Forward

Going forward, there are several basic issues that need to be addressed.

5.1 Appropriate Animal Model with Accurate Readout of Arteriogenesis

Preclinical models that rely on young healthy animals may represent an entirely different biology than that of older human patients with advanced atherosclerosis. Therapeutic modalities

should therefore be evaluated in older, atherosclerotic animals.

The methodology used to assess revascularization should accurately assess collateral development, tissue blood flow, and muscle function. The more commonly used methods of histology and Doppler flow are not sufficiently sensitive or accurate. Newer methods using micro-CT and MRI imaging show considerable promise and should become more widely used. Currently, most methods to assess muscle function in animal models following revascularization are quite crude, relying on so-called semiquantitative ''ambulatory scores'' (e.g. an assessment of toe and foot flexing, dragging, inability to use limb) and ischemic sores (e.g. discoloration, necrosis, amputation). Some reports have used muscle stimulation studies; whether these accurately reflect recovery of muscle function still need further study.

The duration of the animal model should be more representative of the clinical situation. Typically, an animal model is conducted over a 3 to 4 week time frame; in contrast, the clinical trials assess revascularization at 90 and 180 days.

5.2 The Right Growth Factor

The focus, to date, has primarily been on growth factors that stimulate angiogenesis, not arteriogenesis. Thus, although a factor may successfully elicit the local growth of capillaries (which is certainly useful in wound healing), it is unlikely to compensate for the ischemia resulting from a proximal occlusion of a major arterial trunk.

Is VEGF the right growth factor? Are combinations of different growth factors required? As discussed above, there have been promising results from animal studies using combinations of growth factors (e.g. FGF-2 and PDGF-BB, Ang-1 and VEGF, VEGF and HGF). Alternatively, is there an arteriogenesis specific growth factor or stimulus (e.g. a master switch gene)? For a single growth factor to be effective, it would have to initiate a self-propagating cascade of the appropriate proliferative, migratory, and inflammatory responses and orchestrate the responses of several different types of cells involved in the response. Some investigators are evaluating the possible utility of gene therapy using the hypoxia ''master switch'' gene, HIF-1α. However, since arteriogenesis is not triggered by hypoxia, it is unclear whether this strategy will be successful.

Alternative candidates might be found by a more intensive evaluation of the role of monocytes in arteriogenesis. That these cells play a crucial role is underscored by the observations of depressed arteriogenic responses in animals following monocyte depletion, as well as in the CCR-2 null mice (which lack the receptor for the monocyte specific chemotactic factor, MCP-1). Macrophages are known to produce a variety of growth factors and cytokines including bFGF, TGF-α, GM-CSF, M-CSF, VEGF, IL-8, substance P, IGF-1, and PDGF. Nerve growth factor (NGF) has also been described to be proangiogenic and to improve collateral development in animal models of ischemia. Del-1, an integrin receptor ligand, has also been reported to be proangiogenic in animal models.

5.3 The Role/Utility of Bone Marrow-derived Cells

Vasculogenesis was a term that originally referred to a process restricted to embryonic development; however, more recently

it has been used to describe the formation of a primary vasculature from precursor cells in the adult. The contribution of such a process to ongoing angiogenesis and arteriogenesis is quite controversial. The controversies arise from a number of issues, (1) difficulties in defining what precisely is an endothelial precursor cell; (2) the possible role of cell fusion, in which the nuclear contents of two cells can fuse to form a cell with a twofold increase in chromosome content (for some reason circulating bone marrow cells seem to be particularly susceptible to this phenomenon); and (3) sampling or technical issues arising from the assessment of EPC contribution to new vessels. For example, two recent high-power laser confocal studies clearly demonstrated that cells which previously would have been considered as incorporated into newly forming vasculature were actually incorrectly identified because of the overlap of different fluorescent signals from adjacent cells. However, whether bone marrow-derived precursor cells are incorporated into collaterals or contribute to collateral development by some paracrine mechanism, data from several groups now clearly demonstrate that these cells are recruited to regions of collateral development. Thus, the role and importance of these cells to the process is an area in need of intensive investigation.

5.4 Drug Delivery

Translation of ''therapeutic angiogenesis'' from the lab bench to the clinic requires an assessment of what are truly clinically viable delivery strategies. With respect to coronary revascularization, prolonged or frequent repetitive intracoronary infusions are probably not acceptable. Moreover, intravascular delivery is presented with the problems of the endothelial barrier and the rapid washout of the drug. Local perivascular delivery may be more feasible if it could be accomplished noninvasively (e.g. thoracoscopically). Another approach is to instill a growth factor intrapericardially, which can be accomplished with a catheter and it obviates the need for open-chest surgery. However, the patient population that this would be applicable to is limited, since many have had prior coronary artery bypass graft surgery and no longer have a pericardial cavity suitable for such local delivery. Another approach might be intramyocardial delivery. While this has the appeal of delivering the drug to the site where required, it is an invasive approach requiring highly specialized equipment and a highly skilled operator. Sustained release formulations, where the growth factor of interest is incorporated into a polymer or gel, can allow prolonged, local release.

While the use of gene therapy has been touted as a means to get around the problems of protein delivery, gene transfer has its own problems. For example, the efficiency of gene transfer seems to be reduced in ischemic tissues. Aging myocytes demonstrate a decreased efficiency of adenoviral mediated gene expression. The proteins, whether administered directly or produced via gene therapy may also have a reduced half-life in ischemic tissue due to ongoing processes of tissue resorption or repair. A general problem with adenoviral vectors is their immunoreactivity. Expression is lost in most tissues within the first few weeks after gene transfer, although some of the more recent ''second generation'' viral vectors have been reported to last as long as 20 weeks. Further modifications in these vectors may lead to improvements in adenoviral gene transfer.

Improvements in the delivery strategy require an accurate assessment of the amount and residence time of the drug (or other therapeutic agent) delivered to the site. This may be improved by the use of sustained release formulations (for proteins or small molecules) and is clearly necessary when using gene therapy or stem cell therapy. Coadministration of agents such as sodium nitroprusside, serotonin, or acetylcholine should also be considered since these agents appear to increase the efficiency of transfection.

5.5 New Approaches

The use of bone marrow-derived stem cells for therapeutic applications has now been extended to a number of small clinical trials, and the initial data are promising. For example, Miyamoto and coworkers implanted bone marrow–mononuclear cells plus platelets in 12 patients with peripheral arterial disease. The initial results suggested improved blood flow, reduction in pain, and an improvement in walking time. A group in Korea recently published their findings from the Myoblast Autologous Graft in Ischemic Cardiomyopathy (MAGIC) cell-randomized clinical trial. Twenty-seven patients with myocardial infarction who underwent coronary stenting received peripheral blood stem cell infusion ($n = 10$), G-CSF alone ($n = 10$), or control (7). At follow-up, the patients who had received cell infusion improved significantly (indices monitored included exercise capacity, myocardial perfusion, and systolic function) compared to controls. The patients treated with G-CSF also showed an improved cardiac function but had an unexpectedly high rate of in-stent restenosis.

Cell-based gene therapy is a relatively new approach that utilizes autologous cells as vectors following *in vitro* transfection with the transgene of interest. This approach has the advantages of circumventing the inflammatory response through the use of autologous cells. Additionally, stable transfection of the cells helps to achieve a more prolonged expression of the transgene. This approach is also amenable to the use of more complex constructs that could allow a stable, regulatable expression, and also the possibility of expressing more than one transgene. To date, the major approaches for ischemic tissues have used gene transfer by transfected skeletal myoblasts, smooth muscle cells, and angioblasts.

5.6 Patient Selection

The majority of the clinical trials of therapeutic angiogenesis have selected those patients that have undergone multiple failed revascularization attempts including coronary artery bypass graft (CABG) surgery and percutaneous coronary interventions. Is this the population most likely to respond? One might disagree that this may represent a population that is particularly resistant to a new collateral formation or may have utilized (and occluded) preexisting collaterals. Moreover, the time period (probably 2–3 weeks) after the initial therapy that may be required to revascularize may not be applicable to a patient with a life-threatening occlusion of a proximal vessel. A recent consensus panel of experts agreed that the following patient groups may represent better candidates for induction of therapeutic angiogenesis :

1. Patients with single, long-standing occlusion(s) of proximal coronary arteries subtending viable myocardium

2. Patients with multivessel, diffuse disease with evidence of inducible ischemia and myocardial viability
3. Presence of adequate feeder vessels
4. Presence of adequate distal runoff

Therapeutic angiogenesis may also be a preferred therapy in patients with a coronary anatomy that is not suited to angioplasty or surgery. Additionally, there may be genetic factors, as yet not defined, that might play a role in the response to angiogenic stimulation. Clinical studies are always complicated by the complexity of the patients, and one of the background issues in these studies is the possibility that some common medications, such as captopril, aspirin, cyclooxygenase-2 inhibitors, lovastatin, isosorbide dinitrate, and antibiotics might have antiangiogenic effects. A potential risk with proangiogenesis therapy is the possibility that stimulation of new blood vessel growth might also result in undesirable outcomes such as in-plaque angiogenesis, acceleration of proliferative retinopathy or age-related macular degeneration, or cancer. Smokers are commonly known to have a diminished wound healing response, which may make them poor candidates for a therapeutic angiogenesis therapy. The effect of smoking on arteriogenesis has not been studied. All of the clinical studies conducted to date have demonstrated a high variability in response among patients, indicating that there may be some as yet to be determined biological factor(s), which might predict responders. Are there differences, for example, in the local or circulating inhibitors of angiogenesis (e.g. endostatin, angiostatin, platelet factor 4, tumistatin, thrombospondins, $VEGF165_b$)? The search for biomarkers and their validation as predictions of therapeutic response is one of the major issues that need to be addressed to design successful clinical trials.

5.7 Clinical Endpoints

The time-honored endpoint for many cardiovascular trials is ''major adverse cardiovascular events,'' which is a composite endpoint that includes indices including death, myocardial infarctions, recurrent ischemia, and the necessity for intervention. Unfortunately, the complexity of the patient population is such that extremely large and expensive clinical trials would be required to achieve statistical significance. Consequently, clinical endpoints to date have relied on measurements of myocardial ischemia (during exercise testing) and other noninvasive measures of ischemia. These measurements revealed a confounding, potent placebo effect. Potential reasons for a genuine biological improvement in the placebo groups could be due to improved patient care or to the effects of promoting physical activity and exercise (a well-known physiological stimulus for ''therapeutic'' angiogenesis). The development of a surrogate marker that would identify drug effects is a clear challenge. Most clinical investigators believe that a method to image newly formed vessels or developing collaterals directly would provide such a surrogate. Emerging technologies for the noninvasive assessment of vascularity and perfusion, including magnetic resonance imaging, and positron-emission tomography may provide some of these necessary new tools.

6 Conclusion

Therapeutic arteriogenesis thus remains an unproven clinical treatment for both coronary artery disease and peripheral vascular disease. However, there is certainly

a reason to be optimistic. As with any new therapy, scientists and clinicians must learn from the failures and incorporate the lessons learned into new approaches. The questions have now been asked, and only the future will provide the answer.

Keywords

Antibiotics
Chemical substances that inhibit the growth of microorganisms such as bacteria and fungi.

Drug Discovery
The process of identifying molecules that may be used to treat diseases and ailments.

Natural Products
Chemical substances produced by living organisms

Pharmaceuticals
Drugs that are used to treat human diseases or substances having medicinal properties.

Screening
Testing substances for biological activity and their potential use as pharmaceuticals.

Secondary Metabolites
Chemical compounds (natural products) that are not essential for normal growth, development or reproduction of the producing organism.

For most of Nature's flora and fauna, the struggle for survival is often waged at the molecular level. Over time this intense, unending competition has resulted in an armamentarium of small organic molecules with a structural diversity and biological potency often unrivalled by the best efforts and imaginations of scientists. Many of these natural products have proved invaluable in providing templates for the construction of novel drugs with applications in a wide range of therapeutic areas. In fact, the pharmaceuticals derived from microbial and plant secondary metabolites have been directly responsible for doubling life expectancy in the 20th century and more than half of approved drugs are either natural products or related to them. They have revolutionised clinical practice and are still one of the most important sources of anticancer, antiinfective and immunosuppressant agents.

1 Introduction

Of the 520 new pharmaceuticals approved between 1983 and 1994, 39% were derived from natural products, the proportion of antibacterials and anticancer agents of which was over 60%. Between 1998 and 2004, a total of 21 drugs derived from natural products were launched on the market by major pharmaceutical and biotech companies (Table 1), including caspofungin, daptomycin, ertapenem, orlistat, pimecrolimus, rosuvastatin, sirolimus, and telithromycin. In 2000, one-half of the top-selling pharmaceuticals were derived from natural products, having combined sales of more than US $40 billion. These included the biggest selling anticancer drug paclitaxel, the ''statin'' family of hypolipidemics, and the immunosuppressant cyclosporin. Despite the evident success in drug discovery, the popularity of natural products waned significantly from the early 1990s. An increasing number of pharmaceutical companies cut back or terminated their natural product drug discovery programs in favor of screening very large libraries of synthetic compounds generated by combinatorial methodologies. However, quality lead molecules for many drug targets have remained elusive and more recently, much greater emphasis has been placed on accessing smaller numbers of chemical compounds (focused libraries), but which possess predetermined, druglike physicochemical properties. It remains to be seen whether the unique features of compounds that are themselves derived from living organisms will once again feature prominently in industrial drug discovery programs.

The abundance of microbial and plant-derived natural products and their value in medicine are undisputed, but the reason why these complex chemical substances, known as *secondary metabolites*,

Tab. 1 Drugs derived from natural products (1998–2004).

Year	*Generic name (trade name)*	*Disease area*
1998	Orlistat (Xenical®)	Antiobesity
1998	Cefoselis (Wincef®)	Antibacterial
1999	Dalfopristin and quinupristin (Synercid®)	Antibacterial
1999	Valrubicin (Valstar®)	Oncology
1999	Colforsin daropate (Adele, Adehl®)	Cardiotonic
2000	Arteether (Artemotil®)	Antimalarial
2001	Ertapenem (Invanz™)	Antibacterial
2001	Caspofungin (Cancidas®)	Antifungal
2001	Telithromycin (Ketek®)	Antibacterial
2001	Pimecrolimus (Elidel®)	Atopic dermatitis
2002	Galantamine (Reminyl®)	Alzheimer's disease
2002	Micafungin (Funguard®)	Antifungal
2002	Amrubicin hydrochloride (Calsed®)	Oncology
2002	Biapenem (Omegacin®)	Antibacterial
2002	Nitisinone (Orfadin®)	Antityrosinaemia
2003	Miglustat (Zavesca®)	Type 1 Gaucher disease
2003	Mycophenolate sodium (Myfortic®)	Immunosuppression
2003	Rosuvastatin (Crestor®)	Dyslipidemia
2003	Pitavastatin (Livalo®)	Dyslipidemia
2003	Daptomycin (Cubicin™)	Antibacterial
2004	Everolimus (Certican™)	Immunosuppression

are produced has been subject to much debate. One popular view is that these compounds have a specific role in protecting the otherwise defenseless producing organisms from attack by predators. Taking morphine as an example of a secondary metabolite whose value to the producing plant is not entirely obvious, 14 steps are required from available amino acids, including at least one step that is highly substrate specific. The presence of morphine in the tissues of *Papaver somniferum* must therefore, confer a selectional advantage on the plant: genetic code is required for each of the enzymes involved in the biosynthesis, valuable amino acids are utilized in forming the enzymes, and a relatively scarce nutrient (nitrogen) is locked up in the compounds produced. If morphine did not continue to have value for the plant, mutants would have arisen with the advantage of not having a drain on their metabolic resources.

We can only guess at the ecological functions of morphine. Perhaps a mammalian herbivore that consumed too many poppies would become drowsy and itself fall prey to a carnivore. It may be significant that the cannabinoids (CB), produced in greatest abundance in the nutritious growing tips of the plant, also induce mental effects that would compromise a herbivore's ability to escape a predator. Whatever their natural protective functions, natural products are a rich source of biologically active compounds that have arisen as the result of natural selection, over perhaps 300 million years. The challenge to the medicinal chemist is to exploit this unique chemical diversity. The following account illustrates

how natural products have been used as what are called *lead compounds*, or templates for the development of important medicines.

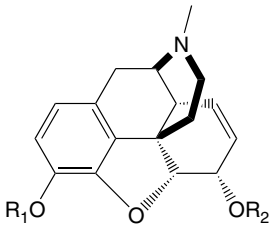
2
Drugs Affecting the Central Nervous System

2.1
Morphine Alkaloids

The history of the opium alkaloids is too well known to warrant repetition here, but the analgesics based on morphine (**1**) are too important to be left out of an account of natural products as leads. Thus, we shall summarize the clinically more important developments that have occurred since the isolation of morphine in 1803. Codeine (**2**) continues to be used widely for the treatment of moderate pain and, although present in the opium poppy (*P. somniferum*), it is normally synthesized in higher yield from morphine.

Other than codeine, the earliest significant semisynthetic derivative of morphine was the diacetate heroin (**3**), which is still used in terminal cancer where its addictiveness is irrelevant. Acetylation masks the polar hydroxy groups, so that penetration into the central nervous system (CNS) is enhanced; hydrolysis then occurs to liberate the phenolic hydroxyl, giving an active analgesic and ultimately regenerates morphine. Heroin was thus one of the first prodrugs.

Modifications to the C-ring of morphine are legion, but none of the derivatives is free from addictive liability, though many have been used clinically. N-Demethylation and realkylation yield more interesting analogs, notably

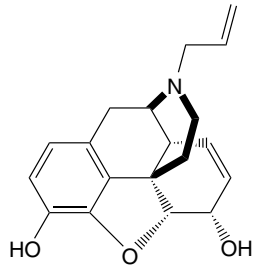


(**1**) Morphine $R_1 = R_2 = H$

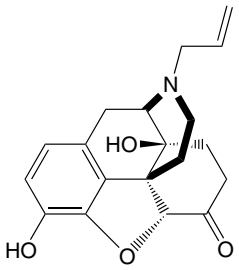
(**2**) Codeine $R_1 = CH_3$, $R_2 = H$

(**3**) Heroin $R_1 = R_2 = COCH_3$

N-allylnormorphine and nalorphine (**4**), which is a morphine antagonist. Further modification leads to naloxone (**5**), which unlike nalorphine has very little agonist activity and has retained a place in therapy for treatment of opiate-induced respiratory depression. Naloxone will also precipitate withdrawal symptoms in opiate addicts, thereby facilitating diagnosis.

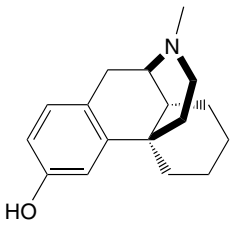


(**4**) Nalorphine

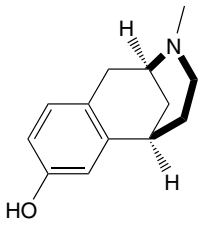


(**5**) Naloxone

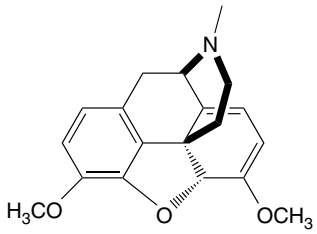
Total synthesis of morphine is difficult, but analogs lacking the dihydrofuran ring are accessible from 1-benzylisoquinolines, in analogy with the biosynthesis of morphine, to give the morphinans (**6**). The system may be simplified even further to give the benzomorphans (**7**), although neither these nor the morphinans have provided the long-sought analgesic without addictive properties.



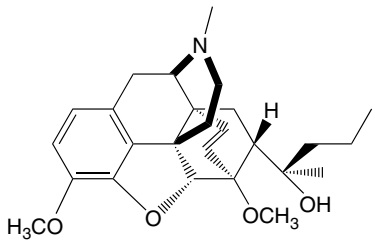
(**6**) Morphinan



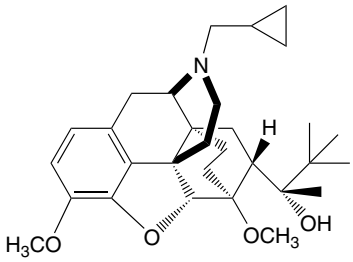
(**7**) Benzomorphan



(**8**) Thebaine



(**9**) Etorphine

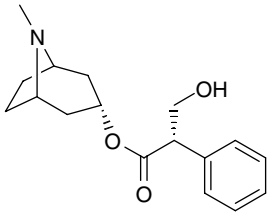


(**10**) Buprenorphine

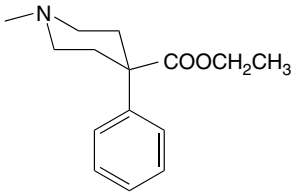
A semisynthetic route to morphine analogs was found from thebaine (**8**) using Diels–Alder reactions in the C-ring. Adducts such as etorphine (**9**) have the distinction of very high potency, sufficient to immobilize rhinoceroses at moderate dose levels! Unfortunately, the addictive liability runs parallel to the increase in analgesic potency, a tendency that was partly overcome in the analog buprenorphine (**10**).

All this work was carried out in ignorance of the nature of the natural transmitter(s) which subsequently, proved to be the peptides known as *endorphins* and their pentapeptide fragments, as the *enkephalins*. It is perhaps significant that vastly improved understanding of the biochemical basis for analgesia and the characterization of a family of related receptors, known as δ, κ, and μ, have so far failed to yield any better drugs for the treatment of pain.

A series of analgesics that were discovered initially in an attempt to obtain smooth muscle relaxants based on another natural product, atropine (**11**),



(**11**) Atropine



(**12**) Pethidine

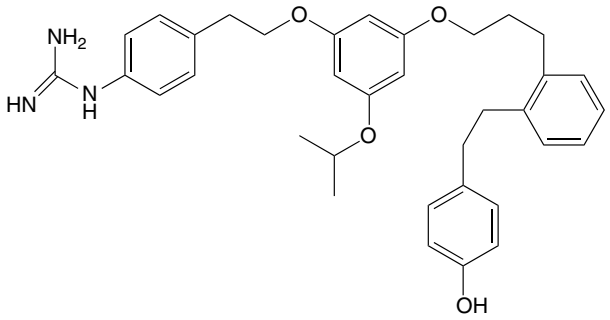
started with the observation that meperidine (pethidine) (**12**) unexpectedly produced a reaction in mice known as *Straub tail*, normally characteristic of the morphine series. Meperidine itself is still used widely in childbirth in the belief that there is a lower incidence of respiratory depression in the fetus. The realization that 4-phenylpiperidines, which are not obvious structural analogs of morphine, could give rise to useful analgesic effects, led to the synthesis of many thousands of derivatives, several with far greater potency than that of meperidine. Unfortunately, as potency increases so does addiction liability, and respiratory depression.

2.2 Conotoxins

Elan Pharmaceuticals has developed the peptide SNX-111 (Ziconotide), the synthetic equivalent of ω-Conopeptide-MVIIA, found in the venom of the predatory marine snail *Conus magus*, for the treatment of severe pain and ischemia. Marketing approval in the United States and Europe has recently been granted for SNX-111 as an intrathecal infusion in the treatment of severe, chronic pain. The peptide has the structure H-^{1}Cys-Lys-Gly-Lys-Gly-Ala-Lys-^{8}Cys-Ser-Arg-Leu-Met-Try-Asp-^{15}Cys-^{16}Cys-Thr-Gly-Ser-^{20}Cys-Arg-Ser-Gly-Lys-^{25}Cys-NH_2 cyclic(1–16), (8–20), (15–25)-tris (disulfide), which does not make it an easy target for synthesis and gives it poor distribution properties *in vivo*.

SNX-111 blocks N-type calcium channels, which are located throughout the CNS on neuronal somata, dendrites, dendritic spines, and axon terminals, where they play a major role in the regulation of the *neurotransmitters* associated with pain transmission and stroke. The drive is to discover an orally active, selective, small-molecule modulator of N-type calcium channels to overcome the disadvantages of administration of SNX-111.

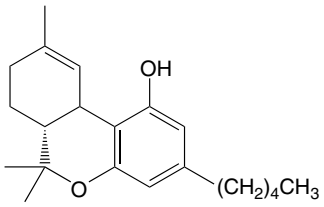
High-throughput *screening* campaigns have resulted in a number of leads being identified; whereas others have chosen to modify known drugs shown to block N-type channels. Workers at Parke-Davis, however, employed a ligand-based approach using the three-dimensional solution structure of the peptide. Compounds such as conotoxin analog (**13**) were designed where key binding motifs are attached to an alkylphenyl ether scaffold. The compound had an IC_{50} value of 3.3 μM in a human N-type channel assay, but showed no selectivity over the L-type channel. Structure-activity work on the conotoxins has shown that other regions of the peptide, absent in these synthetic ligands, are responsible for channel family selectivity.



(**13**) Conotoxin analog

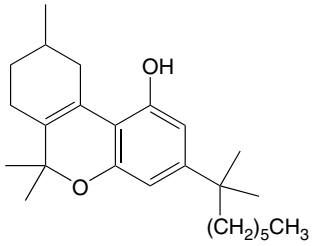
2.3 Cannabinoids

The plant *Cannabis sativa* has been used by humans for thousands of years, both for the effects when ingested and for making rope from the fibers in the stem. The major constituent of pharmacological interest is Δ_9-tetrahydrocannabinol (**14**) (THC), which has a multiplicity of actions. In animals, the effects include sedation and apparent hallucinations, which are similar to the major effects in the CNS in humans. There are also cardiovascular effects, notably tachycardia and postural hypotension, which can be separated from the CNS action, as in the synthetic analog $\Delta_{6a,10a}$-dimethylheptyl-THC (**15**), which has minimal CNS activity.



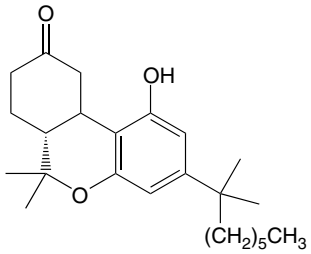
(**14**) THC

Given the widespread illicit use of *C. sativa*, it was perhaps inevitable that eventually one or two cancer patients receiving chemotherapy would dose themselves with their own sedative in the form of marijuana. An unexpected blessing from this uncontrolled combination was a reduction in the nausea experienced during chemotherapy. A variety of anticancer agents cause severe nausea and vomiting, including nitrogen mustard, adriamycin, 5-azacytidine, cyclophosphamide, and methotrexate: a unique situation arose in which the remedy was discovered by the patients themselves. Although smoking reefers gives rapid absorption and close control of the effects, smoking cannot be recommended and thus, when the physicians in charge were made aware of their patients' discovery, they devised a controlled clinical trial in which measured doses of THC were dissolved in sesame oil and administered in gelatin capsules. A placebo was similarly prepared for use in a randomized, double-blind, cross-over



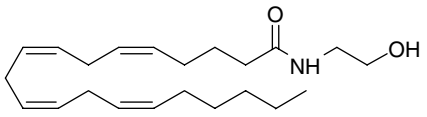
(**15**)

experiment. The results left no doubt that a majority of patients benefited from THC pretreatment, even those who had previously been refractory to the effects of the standard antiemetics such as prochlorperazine. There remained the problem of tachycardia associated with THC treatment. The multiplicity of effects of THC has led to the synthesis of large numbers of analogs, particularly in the hope of finding nonmorphine-like analgesics without addictiveness and without the other CNS effects of THC. The analog nabilone (**16**) had been shown to exert less effect than that of THC on the cardiovascular system, while retaining the mixture of CNS actions, including analgesic, antianxiety, and antipsychotic properties. When tested as an antiemetic, nabilone proved to be superior to THC and has been used for this purpose for more than 30 years.

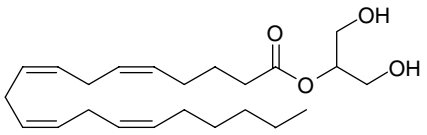


(**16**) Nabilone

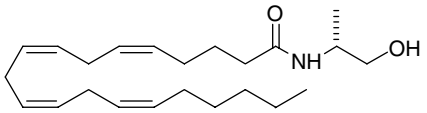
After the demonstration of THC binding sites in the CNS, a search for an endogenous ligand produced the long-chain ethanolamine derivative (**17**) of arachidonic acid, known as *anandamide*. Subsequently, the glycerol ester of arachidonic acid (**18**), known as *2-AG*, was shown to be a more abundant endogenous ligand in the brain than anandamide. Further development has tended to concentrate on analogs of the natural ligands, notably the methyl derivative of anandamide (**19**), which is resistant to the amide hydrolase that terminates the action of anandamide itself and the dimethylheptyl analog (**20**) that is traceable to the earlier modifications to THC. Such analogs tend to have activity similar to that of THC.



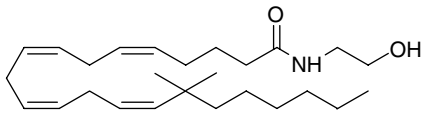
(**17**) Anandamide



(**18**) 2-AG

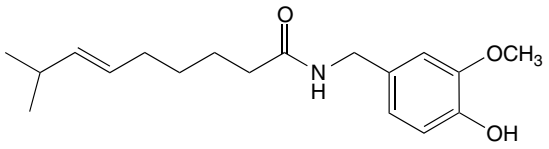


(**19**) *R*-methanandamide



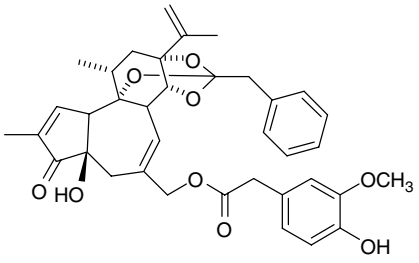
(**20**)

An interesting twist in the tail is provided by the observation that anandamide is also a ligand for the so-called *enigmatic vanilloid receptors*, previously characterized through their interactions with two other natural

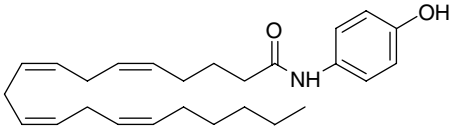


(**21**) Capsaicin

products, capsaicin (**21**) and resiniferatoxin (**22**) responsible for the ''hot'' sensation caused by compounds in, for example, chillies. A functional vanilloid receptor was cloned in 1997 and is activated by heat and acid as well as the chemical ligands. A combination of the anandamide structure with a vanilloid motif, as in AM404 (**23**), enhances the anandamide transport inhibitory properties. The situation is complex from the viewpoint of drug design, not least because there are two cannabinoid receptors, plus a hydrolase and a transport protein, interference with any or all of which might provide new drugs.



(**22**) Resiniferatoxin



(**23**) AM404

The cannabinoid acids, which are devoid of psychotropic activity, are promising anti-inflammatory agents and it is possible that the next useful therapeutic agent will come from this direction, rather than the sought-after analgesic.

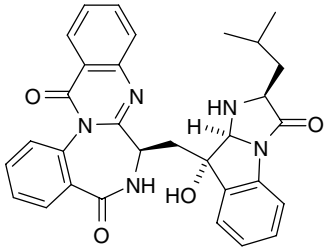
2.4 Asperlicin

Cholecystokinin (CCK) is a peptide hormone, present in the gut and CNS; it is one of the most abundant peptides in the brain. The whole peptide is composed of 33 amino acids, but the C-terminal octapeptide H-Asp-Tyr(SO_3H)-Met-Gly-Trp-Met-Asp-Phe-NH_2 possesses the full range of activities, sufficient for it to be classed as a *neurotransmitter*. Specific, high-affinity binding sites have been found on mammalian CNS cell membranes and in other organs such as pancreas, gall bladder, and colon. The latter have been classed as CCK-A receptors, but the majority of CNS receptors were classed as CCK-B, on the basis of affinity differences for various agonists and antagonists. To confuse the issue slightly, the gastrin receptor in the stomach is closely related to the CCK-B (now known as the CCK_2) receptor and is stimulated by the C-terminal tetrapeptide of CCK: in the periphery, gastrin receptors are the same as CCK_2 receptors.

The effects of CCK on intestinal smooth muscle and pancreas are easy to demonstrate pharmacologically, unlike the role in the CNS, which is a matter for conjecture. It was assumed that the CNS activity must be significant, given the abundance of the

peptide in the brain and that the discovery of antagonists might lead to new drug treatments, as yet unspecified.

Fishing in microbial broths, using radioreceptors as bait, produced asperlicin (**24**), the first potent, competitive, and selective CCK-A (CCK_1) antagonist, from a culture of *Aspergillus alliaceus*.

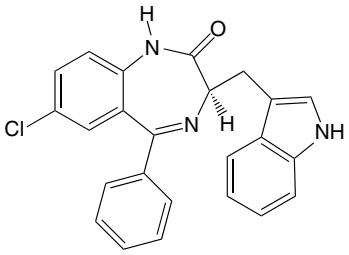


(**24**) Asperlicin

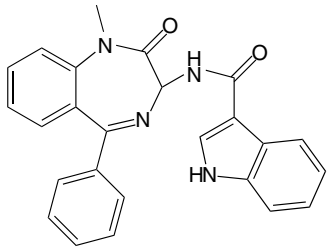
Asperlicin is moderately potent, poorly soluble in water, and not bioavailable by the oral route. When discovered it was also, with morphine, one of the very few nonpeptides with affinity for a peptide receptor (peptoids are discounted in this assessment). It was an interesting target for synthetic modification, particularly viewed as a benzodiazepine derivative with potential CNS activity.

On the basis of the benzodiazepine nucleus and an overt mimic of diazepam, one of the first successful synthetic analogs was L-364,286 (**25**), which had potency on CCK-A receptors similar to that of asperlicin. Better receptor affinity was achieved with 3-amide–substituted benzazepines: the 2-indolyl derivative L-364,718, also known as MK-329 (**26**), is 5 orders of magnitude more potent than asperlicin at CCK-A receptors and is a valuable pharmacological tool.

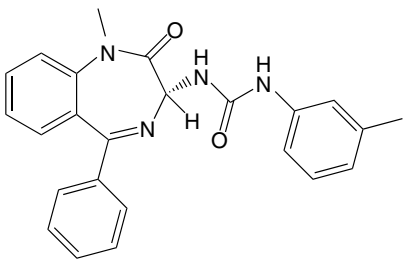
Modification of the 3-amide to give a urea linkage as in (**27**) led to a reduction in CCK-A receptor affinity. Importantly, discrimination between CCK-A and CCK-B receptors by (**27**) is governed by the stereochemistry at C3, the (S)-enantiomer showing greater affinity for CCK-A receptors. The (R)-enantiomer, known as L-365,260, prefers CCK-B receptors, antagonizes gastrin-stimulated acid secretion in animal models and, among other CNS effects, induces analgesia in primates and displays anxiolytic properties.



(**25**)

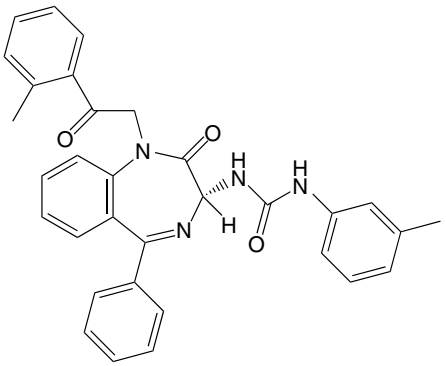


(**26**)



(**27**)

Further development in this series has substantially improved receptor affinity:



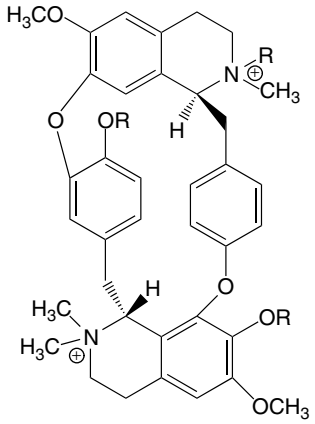
(**28**) YM-022

YM-022 (**28**) has IC_{50} 0.05 nM kg^{-1}. Clinical trials of compounds in this series have been disappointing because of poor bioavailability, but the general concept of finding a therapeutic agent through antagonism of CCK_2 receptors is still viable.

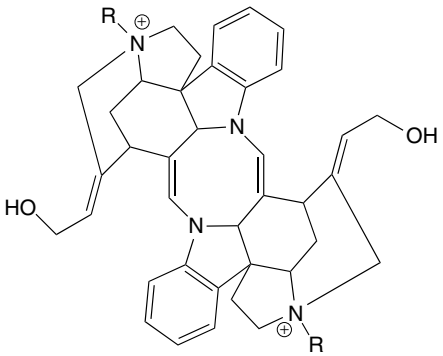
3
Neuromuscular Blocking Drugs

3.1
Curare, Decamethonium, and Atracurium

The development and use of muscle relaxants, to allow a reduction in the level of anesthesia during surgery, follows entirely from studies of South American arrow poisons and particularly from the isolation of pure D-tubocurarine (**29**) in the 1930s from tube curare. Another of the South American blowpipe poisons, *calabash curare*, was used for similar purposes and developed to give alcuronium (**30**) from the alkaloid C-toxiferine 1 (**31**). Both types of curare paralyze skeletal muscle by a similar mechanism, antagonizing the effect of acetylcholine at the neuromuscular junction.



(**29**) Tubocurarine R = H
(**32**) Metocurine R = CH_3

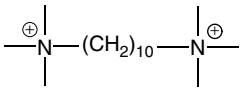


(**30**) Alcuronium R = $CH_2CH{=}CH_2$
(**31**) C-toxiferine 1 R = CH_3

The muscle-paralyzing curare alkaloids are quaternary salts that are not absorbed when taken orally. For surgical procedures, they must be administered by intravenous injection, which results in onset of paralysis in at most a few minutes: anesthesia is normally induced before administration of the muscle relaxant, which is followed by artificial respiration. Although the neuromuscular blocking agents are potentially lethal when administered alone, in the environment of an operating theater they are truly lifesaving drugs that have made

a major impact on survival rates during surgery.

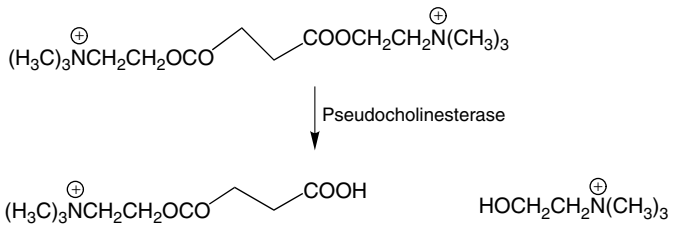
In the 1930s, there were no spectroscopic aids to structure elucidation and it is not surprising that an error was made assigning two quaternary nitrogens to the structure of d-tubocurarine, a mistake that was not corrected until 1970. The methylation product of d-tubocurarine, known as *metocurine* (**32**), is a more potent muscle relaxant. It was known for a long time as dimethyltubocurarine because of the erroneous structure allocated to compound (**29**). The error, in assigning a bisquaternary structure to a molecule with one quaternary and one protonated tertiary nitrogen, led to a large number of highly active synthetic bisquaternaries. The simplest of these was decamethonium (**33**), which was nothing more than two trimethylammonium end groups connected with a decamethylene chain. As one of a series with different chain lengths, decamethonium became the prototype for many more complex structures with 10 atoms between the quaternary centers, which appeared to be optimal for binding to the acetylcholine receptor at the neuromuscular junction.



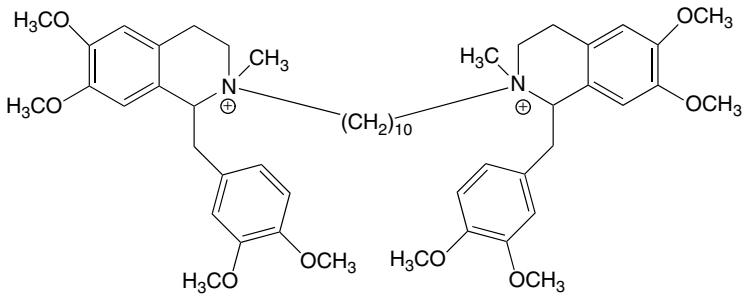
(**33**) Decamethonium

Unlike tubocurarine, decamethonium depolarizes the muscle endplate, rendering the membrane insensitive to acetylcholine. The action of tubocurarine is competitive and can be overcome with increased concentrations of acetylcholine, brought about by administration of an anticholinesterase: the latter is thus, an antidote to tubocurarine, but not to decamethonium. Despite the lack of an antidote, decamethonium was used very widely for over two decades. One of its disadvantages is an overlong duration of action, during which time the patient has to be maintained on artificial respiration, because the muscle of the diaphragm is also susceptible to the actions of the drug. An early and highly successful attempt to shorten the action of decamethonium gave suxamethonium (**34**), a diester formed between succinic acid and two molecules of choline, which hydrolyzes rapidly in the presence of pseudocholinesterase.

Tubocurarine causes cardiovascular side effects induced by direct interactions with ganglionic acetylcholine receptors and from stimulation of histamine release, so analogs have been well worth pursuing. The macrocyclic structure of tubocurarine is a difficult synthetic target, but fortunately, ring-opened analogs, such as laudexium (**35**), have high potency and relatively few side effects. The main problem with (**35**) is the duration of action, which

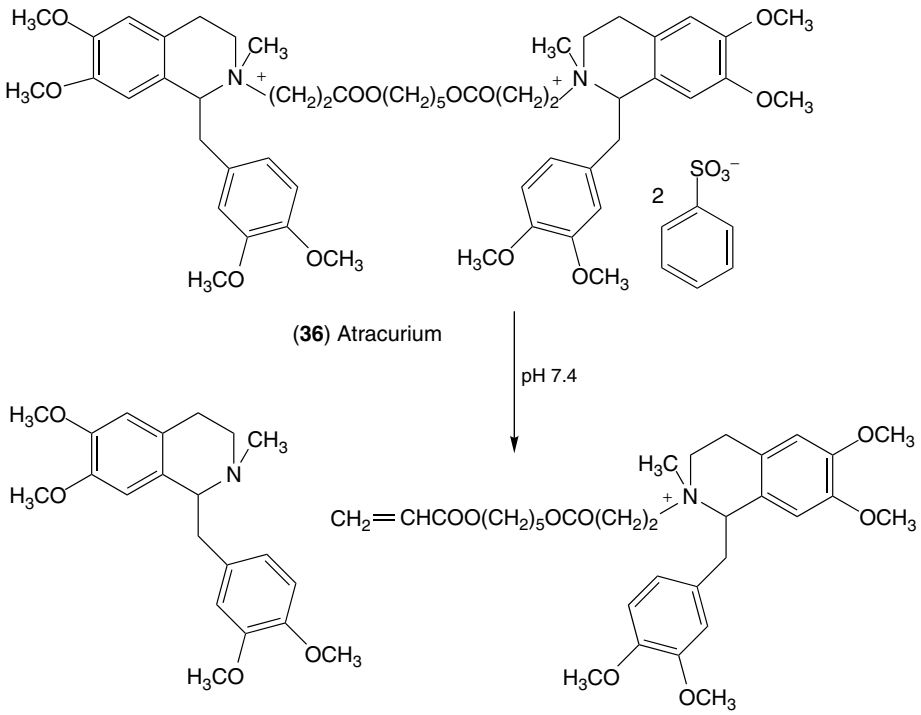


Decomposition of suxamethonium (**34**)

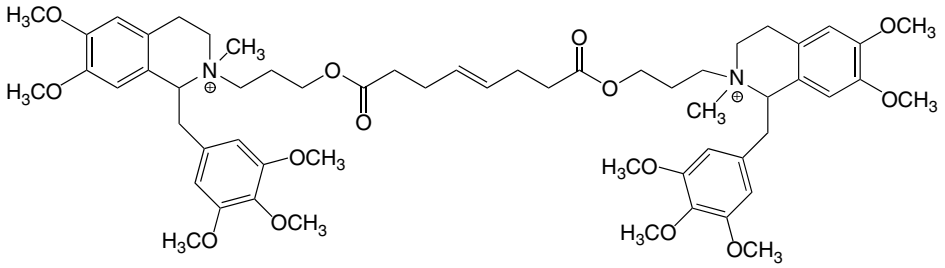


(**35**) Laudexium

at about 40 min is too long for many operations. Two approaches have been used to shorten the duration of action. The concept of pH-controlled Hofmann elimination was employed successfully in the design of atracurium (**36**), which in clinical use has the advantage that the drug disappears at a constant rate, irrespective of liver or kidney function. Some ester hydrolysis contributes to the degradation of atracurium *in vivo*, as might be expected. A slightly later development centered on an empirical search for structures that would undergo ester hydrolysis more rapidly, resulting in mivacurium (**37**), which has a slightly shorter duration of action than that



(**36**) Atracurium



(**37**) Mivacurium

of atracurium, the latter being about 15 to 20 min.

4 Anticancer Drugs

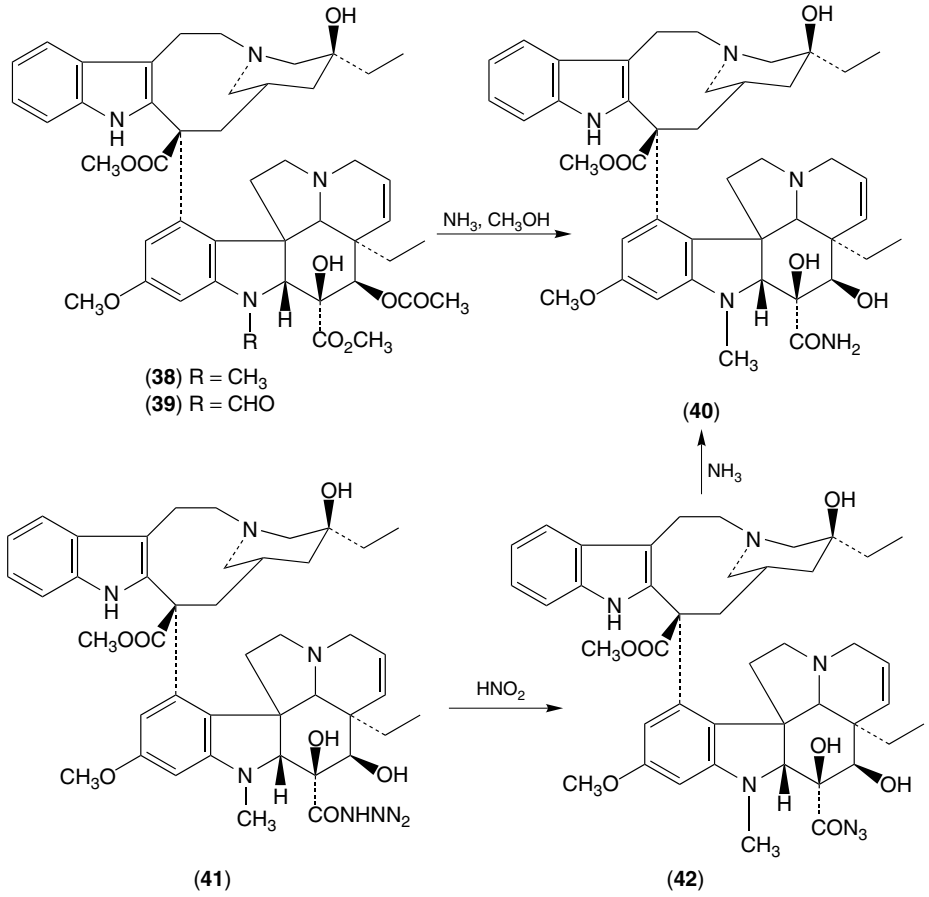
4.1 Catharanthus (Vinca) Alkaloids

In 1949, Canadian researchers at the University of Western Ontario began investigating the medicinal properties of the rosy periwinkle (*Catharanthus roseus*), a plant that had been used for many years to treat diabetes mellitus in the West Indies. Despite finding that the plant extract when given orally had no effect on blood sugar levels in rats or rabbits, the researchers noted that when given intravenously, the extract caused the animals to succumb to bacterial infection and die. This curious observation prompted further studies, which showed that the plant extract reduced levels of white blood cells, causing granulocytopenia and bone marrow damage, toxic effects that are encountered with many antitumor drugs. These findings led the Canadian group to isolate an alkaloid fraction with potent cytotoxic activity. The active principle was eventually purified and became known as *vinblastine* (**38**), a dimeric indole-dihydroindole alkaloid.

Concurrently, researchers at the Lilly Research Laboratories had been investigating extracts of *C. roseus* and they too had detected cytotoxic activity, specifically against acute lymphocytic leukemia. The US group isolated several alkaloids, including vinblastine and another closely related alkaloid, vincristine (**39**).

Although many other alkaloids have been isolated from *C. roseus*, only vinblastine and vincristine have been developed for clinical use. The antiproliferative activity of the two compounds is related to their specific interaction with tubulin, thus preventing assembly of tubulin into microtubules and arresting cell division. However, despite this apparent identical mechanism of action and their clear chemical similarities, vinblastine and vincristine display very different clinical effects. Vinblastine, for example, is used to treat Hodgkin's disease and metastatic testicular tumors, whereas vincristine is used mainly in combination with other anticancer drugs for the treatment of acute lymphocytic leukemia in children. Toxicity profiles are also different, in that vinblastine causes bone marrow depression, whereas peripheral neuropathy often proves to be dose limiting in vincristine therapy.

Lilly introduced vinblastine and vincristine into the clinic in 1960 and 1963 respectively, but this did not preclude



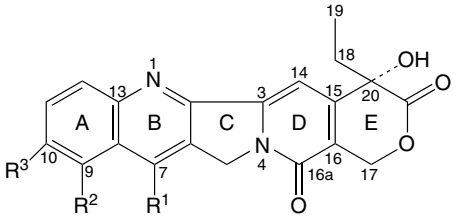
the search for improved derivatives. A chemical modification program aimed at improving antitumor activity and reducing toxicity was initiated in 1972. Concern about the neurotoxicity displayed by vincristine, its chemical instability, and low natural abundance (0.03 g kg^{-1} dried plant material) led to vinblastine being chosen as a template for semisynthetic modification. Selective ammonolysis of the ester function at C-3 and hydrolysis of the adjacent acetyl group yielded the desacetyl vinblastine amide, vindesine (**40**). Better yields of vindesine were obtained from the hydrazide (**41**) on treatment with nitrous acid and then reacting the resultant azide (**42**) with ammonia. The azide (**42**) proved to be a useful intermediate for the preparation of a range of substituted amides, although vindesine proved to be the derivative of choice, with significant differences in the spectrum of antitumor activity and toxicity compared to that of the naturally occurring alkaloids. Phase I clinical trials commenced in 1977 and vindesine has been used for the treatment of non–small cell lung cancer, lymphoblastic leukemia, and

non-Hodgkin's lymphomas. In combination with cisplatin, vindesine ranks among the foremost treatments for non–small cell lung cancer with respect to response rate and survival. Back in the 1950s, the US researchers could not have guessed that 30 years on, the demand for Catharanthus alkaloids would necessitate the processing of around 8000 kg of plant material per year!

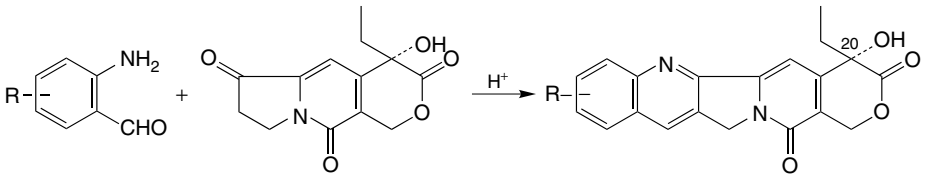
4.2 Camptothecin

Camptothecin (**43**) was first isolated by Monroe Wall and Mansukh Wani in 1966, after ethanolic extracts of *Camptotheca acuminata*, a tree native to China, showing unusual and potent antitumor activity. Starting with 19 kg of dried wood and bark, Wall and Wani painstakingly purified the principal active component with a combination of hot solvent extraction, an 11-stage Craig countercurrent partition process, silica gel chromatography, and crystallization. Camptothecin was characterized as a novel pentacyclic alkaloid, present as just 0.01% w/w of the stem bark of *C. acuminata*. Of particular note was the unusual activity that camptothecin displayed in L1210 and P388 mouse leukemia life-prolongation assays. The compound also inhibited the growth of solid tumors *in vivo* and the water-soluble sodium salt was progressed to phase II clinical trials before being withdrawn because of severe bladder toxicity.

Interest in camptothecin gained new impetus in 1985, when it was discovered that the compound exerts its antitumor activity through a novel mechanism of action. Camptothecin binds to the covalent complex formed by topoisomerase I and DNA, which initiates DNA replication and thus, stabilizes the enzyme–DNA complex and prevents cell proliferation. The elucidation of the mechanism of action provided a means of evaluating camptothecin analogs as topoisomerase inhibitors *in vitro* and efforts then focused on synthesizing water-soluble analogs with broad-spectrum antitumor activities. The α-hydroxy lactone (ring E) and, in particular, the 20 (S)-form proved essential for maintaining biological activity, but the 10-hydroxy analog (**44**) showed greater activity than that of (**43**). Wall and Wani successfully deployed the Friedlander reaction between substituted 2-aminobenzaldehydes and the tricyclic intermediate (**45**), to synthesize a variety of ring-A–substituted analogs. These studies may have prompted SmithKline Beecham (now GlaxoSmithKline) to synthesize the water-soluble 10-hydroxycamptothecin analog topotecan (**46**) that was first approved in 1996 for the treatment of recurrent ovarian cancer and, two years later, for small cell lung cancer. Irinotecan (**47**), developed by Daiichi and Yakult Honsha in Japan and marketed by Pharmacia, was also approved in 1996 for the treatment of advanced colorectal cancer. Irinotecan is inactive as a topoisomerase I inhibitor, but acts as a prodrug of the active 7-ethyl-10-hydroxycamptothecin (**48**).

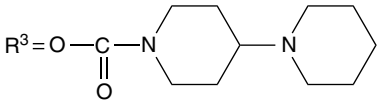


(**43**) Camptothecin: $R^1 = R^2 = R^3 = H$
(**44**) 10-Hydroxycamptothecin: $R^1 = R^2 = H$, $R^3 = OH$



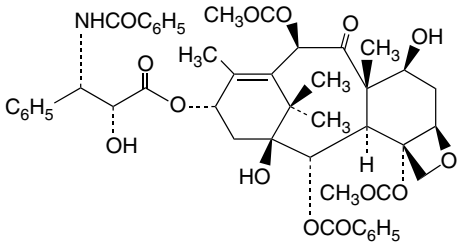
(**45**)

(**46**) Topotecan: $R^1 = H$, $R^2 = CH_2—N(CH_3)_2$, $R^3 = OH$



(**47**) Irinotecan: $R^1 = C_2H_5$, $R^2 = H$,

(**48**) 7-Ethyl-10-hydroxycamptothecin: $R^1 = C_2H_5$, $R^2 = H$, $R^3 = OH$



(**49**)

4.3 Paclitaxel and Docetaxel

Regarded as the tree of death by the Greeks and used to prepare arrow poison by the Celts, the yew tree has been associated with death and poisoning for centuries. The English yew, *Taxus baccata*, was used to make funeral wreaths and it was believed that one could die by merely standing beneath the boughs of the tree.

Yew certainly contains highly toxic metabolites and their potency and fast duration of action has often made extracts of yew the poison of choice for numerous murders and suicide attempts. It is thus, ironic that extracts from the Pacific yew, *Taxus brevifolia*, after being tested in the National Cancer Institute's (NCI) screening program during the 1960s, yielded one of the most exciting anticancer compounds discovered in recent years; that is, paclitaxel (**49**) (originally given the name taxol by Wall and Wani).

The initial isolation and characterization of paclitaxel proved particularly difficult because of (1) its very low natural abundance in *T. brevifolia* bark (although this was the best-known source, the isolated yield was only 0.02% w/w, equivalent to 650 mg per tree); (2) the poor analytical data obtained from the purified compound; and (3) the failure of paclitaxel to give crystals that were suitable for X-ray analysis. The structure of paclitaxel was published in 1971, but further biological testing continued to be troubled by difficulties. The compound showed only modest *in vivo* activity in various leukemia assays, which was no better than that displayed by a number of other new compounds at the time. In addition to the limited supplies of paclitaxel (the complexity of the molecule precluded chemical synthesis), the compound was very poorly soluble in water, which made formulation difficult. However, various new assays were developed in the 1970s, including the murine B16 melanoma model, in which paclitaxel showed very good activity and another boost came when Horwitz et al. discovered that the compound prevented cell division by a unique mode of action. In contrast to the antimitotic vinblastine

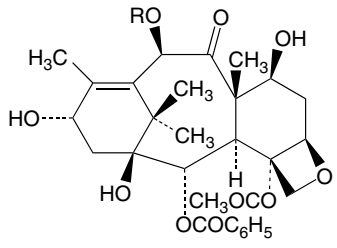
and podophyllotoxin analogs (qv), which prevent microtubule assembly, paclitaxel inhibits cell division by promoting assembly of stable microtubule bundles, which leads to cell death.

Phase I clinical trials were initiated in 1983, but these were to proceed at a slow and tortuous pace and proved all but disastrous when the high levels of oil-based adjuvant used to formulate paclitaxel caused severe allergic reactions in many volunteers. Undaunted by the formulation problem and spurred on by paclitaxel's novel mechanism of action, clinicians were eventually able to minimize the allergic events and demonstrate useful activity. Phase II clinical trials began in 1985 despite continuing supply problems and 4 years later the program received a significant boost when good responses were reported from patients suffering from refractory ovarian cancer, a disease that kills some 12 500 women a year in the United States alone.

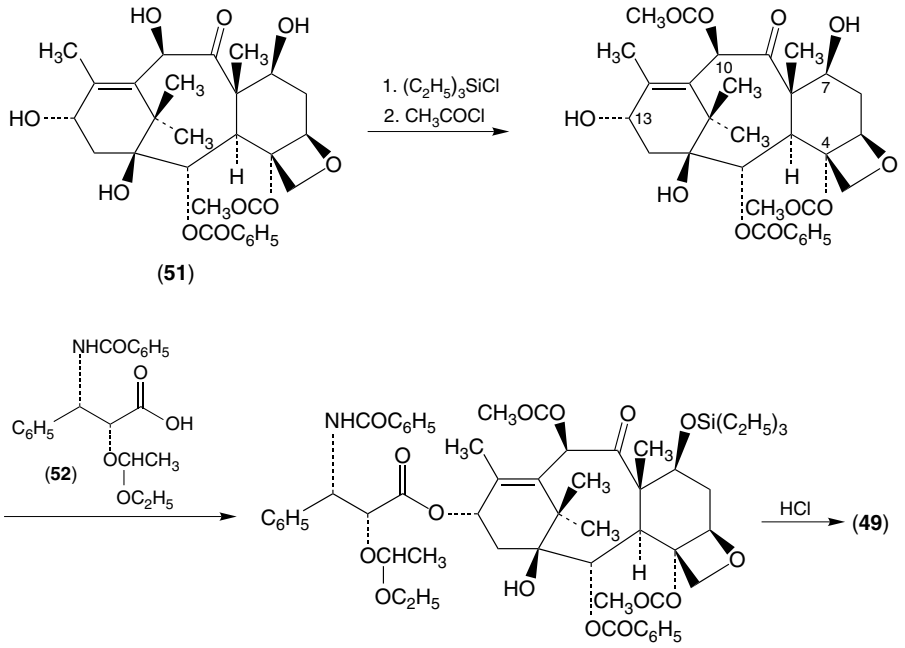
In many ways, the development of paclitaxel mirrored that of the camptothecin analogs, both being dogged for many years by supply issues, poor pharmacokinetics, and toxicity, but the subsequent uncovering of novel mechanisms of action fueled renewed efforts to develop these leads into important new anticancer agents.

In 1991, Bristol-Myers Squibb in conjunction with the NCI agreed to manage the supplies of paclitaxel and they were granted a licence to further develop the compound. The following year the US Federal Drug Administration approved paclitaxel for the treatment of ovarian cancer in patients unresponsive to standard treatments and in December 1993 approval was given for the treatment of metastatic breast cancer.

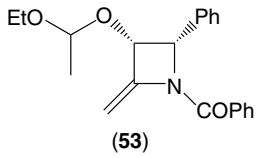
The sourcing of paclitaxel from *T. brevifolia* was a major problem because to treat the groups of patients suffering ovarian cancer in the United States alone would require about 25 kg of compound per year, necessitating the felling of some 38 000 trees! Although the Pacific yew is not a rare tree, it is extremely slow growing and such harvesting could not be sustained indefinitely. It has been estimated that there were enough trees available to maintain a supply of paclitaxel for only 2 to 7 years. The isolation of paclitaxel from other Taxus species has been investigated at length and reasonable quantities have been obtained from the needles of several species including *T. baccata*. Using the needles has alleviated the supply problem because they can be harvested without damaging the tree. However, the needles contain much higher quantities of several biosynthetic precursors of paclitaxel and two of these, baccatin III (**50**) and 10-desacetylbaccatin III (**51**) have been used to prepare paclitaxel semisynthetically. One approach, developed by Potier et al., involved acylation of the sterically hindered C-13 position of baccatin III with cinnamic acid and subsequent double-bond functionalization through hydroxyamination, to give paclitaxel together with various regio- and stereoisomers. A better approach involved protection of 10-desacetylbaccatin III as the triethylsilyl ether, followed by direct acylation with the phenylisoserine derivative (**52**), giving paclitaxel in 38% overall



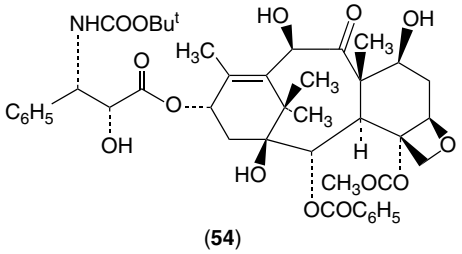
(**50**) R = $COCH_3$
(**51**) R = H



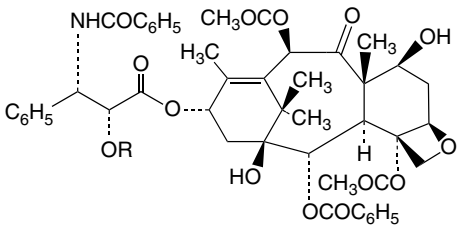
yield. Further improvements were made using less sterically demanding acylating reagents; for example, acylation with the β-lactam (**53**) gave paclitaxel in up to 90% yield and this may be the preferred method for commercial production.

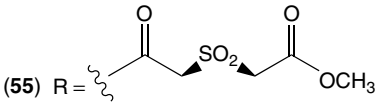


These semisynthetic approaches also provide access to analogs with potential advantages over paclitaxel itself. Structure-activity studies have shown that, although the oxetane ring appears to be essential for activity, wide variation in the nature and stereochemistry of the C-13 ester side chain can be tolerated. Thus, the *N-t*-(butoxycarbonyl) derivative, docetaxel (**54**), which appears to be more potent than paclitaxel and has better solubility characteristics, has been developed and launched by Sanofi-Aventis for the treatment of ovarian, breast, and lung cancers.



Various "protaxols," designed to release paclitaxel *in situ* under physiological conditions, have been prepared by acylating the C-2′ hydroxyl group. Nicolaou et al. reported the synthesis of the sulfone (**55**), which is soluble and stable in aqueous



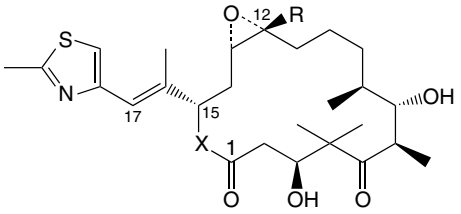


media, but is able to release paclitaxel rapidly in human blood plasma.

Plant tissue culture, microbial fermentation, and total synthesis provide other possibilities for the production of paclitaxel and its derivatives, although it is far from certain whether any of them will be commercially viable.

4.4 Epothilones

Epothilones A (**56**) and B (**57**), 16-membered macrocyclic polyketide lactones, were first isolated from the cellulose-degrading myxobacterium *Sorangium cellulosum* by Hoefle, Reichenbach, and coworkers as narrow-spectrum antifungal and cytotoxic metabolites. The compounds were then tested by the National Cancer Institute in the United States and found to be highly active against breast and colon cancer cell lines. Subsequently, Bollag et al. at the Merck Research Laboratories discovered that the epothilones stabilize microtubule assembly and thus, inhibit cell division by the same mechanism as that of paclitaxel (mentioned earlier). This observation, together with their less complex chemical structure, increased water solubility, more rapid action *in vitro*, and effectiveness against multidrug-resistant tumor cell lines, has prompted significant interest and a number of epothilones are currently undergoing clinical trials as anticancer agents.

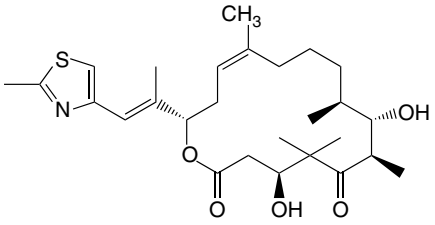


(**56**) Epothilone A: X = O, R = H
(**57**) Epothilone B: X = O, R = CH_3
(**59**) BMS-247550: X = NH, R = CH_3

On learning the absolute stereochemistry of (**56**) and (**57**), three academic research groups embarked on the total synthesis of the epothilones. Nicolaou, Danishefsky, and Schinzer independently adopted successful, elegant synthetic approaches involving olefin metathesis, macrolactonization, Suzuki coupling, or ester–enolate–aldehyde condensation. Within 3 years of the disclosure of their absolute stereochemistry, 17 different total syntheses of the natural products were reported. These syntheses paved the way for the generation of a large number of epothilone analogs for biological evaluation, including the use of solid-phase combinatorial approaches.

The academic groups focused on modifications around the core macrocyclic lactone, establishing important structure–activity relationships, but not improving on the *in vitro* biological activity of the most active natural product, epothilone B (**57**). *In vivo* biological data were comparatively scarce and, although one group reported that epothilones B (**57**) and D (**58**) showed activity in murine tumor models,

researchers at Bristol-Myers Squibb reported that epothilones D (**58**) lacks *in vivo* activity as a result of rapid metabolic inactivation. It was postulated that esterase-mediated hydrolysis of the macrocyclic lactone formed an inactive ring-opened species and, therefore, efforts were focused on replacing the lactone with a more stable macrocyclic lactam moiety. Several macrocyclic lactam derivatives were synthesized from (**57**) and (**58**). Of note was the preparation of BMS-247550 (**59**) in a three-step synthesis from epothilone B (**57**), utilizing a novel Pd(0)-catalyzed ring-opening reaction followed by reduction and macrolactamization. BMS-247550 (**59**), which is in phase III clinical trials, retains its activity against human cancer cells that are naturally insensitive to paclitaxel or that have developed resistance to paclitaxel, both *in vitro* and *in vivo*.



(**58**) Epothilone D

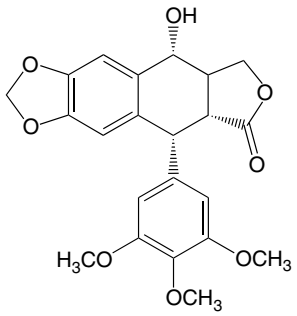
4.5 Podophyllotoxin, Etoposide, and Teniposide

The development of the natural constituents of podophyllum resin into effective semisynthetic and, ultimately, totally synthetic compounds for the treatment of various kinds of cancer provides one of the most sustained and intriguing stories of drug discovery. The story has all the classic ingredients, starting with observation and reasoning, extending through chance into new areas and characterized throughout by persistence and determination, particularly when biological activity had to be traced to very minor constituents in the crude plant extract.

Podophyllum peltatum (Mayapple, or American mandrake) and *Podophyllum emodi* are, respectively, American and Himalayan plants, widely separated geographically, but used in both places as cathartics in folk medicine. An alcoholic extract of the rhizome known as *podophyllin* was included in many pharmacopoeias for its gastrointestinal effects; it was included in the U.S.P., for example, from 1820 to 1942. At about this time the beneficial effect of podophyllin, applied topically to benign tumors known as *condylomata acuminata*, was demonstrated clinically. This usage was not inspirational, given that there are records of topical application in the treatment of cancer by the Penobscot Indians of Maine and, subsequently, by various medical practitioners in the United States from the nineteenth century. The crude resinous podophyllin is an irritant and unpleasant mixture unsuited to systemic administration.

The first chemical constituent was isolated from podophyllin in 1880 and named *podophyllotoxin*. A structure was proposed in 1932 and after some fine-tuning, was shown to be the lignan (**60**). As might be expected, the crude resin contains a variety of chemical types, including the flavonols, quercetin, and kaempferol. Although these other constituents undoubtedly have biological activity, it is the lignans that have received most attention and to which we shall devote the remainder of this section.

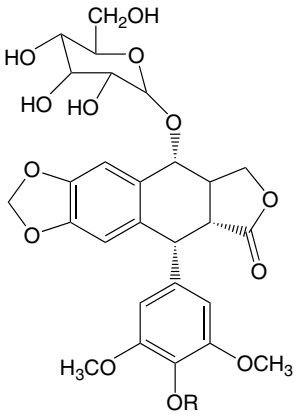
Chemists at Sandoz in the early 1950s reasoned that crude podophyllin might contain lignan glycosides with anticancer activity, which might be more water soluble and less toxic than podophyllotoxin.



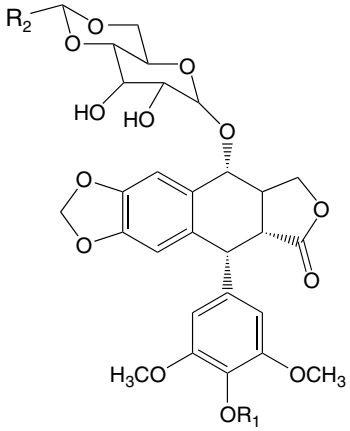
(**60**) Podophyllotoxin

The reasoning for the latter is not entirely clear, but in the event, they proved to be correct in both respects. Careful isolation gave podophyllotoxin β-D-glucopyranoside (**61**) its 4′-desmethyl analog (**62**), and some less important lignans lacking the B-ring hydroxy group. Unfortunately, the sugar derivatives were less active as inhibitors of cell proliferation than were the aglycones, as well as less toxic; however, as expected, they were much more water soluble. While continuing work to isolate more natural lignans, a substantial program of structural modification of the known compounds was undertaken with a view to protect the glucosides from hydrolytic enzymes and also to improve cellular uptake. Most of these changes were ineffective: the per-acylated derivatives, for example, were insoluble in water and had inferior cytostatic effects.

Condensation of the glucosides with a variety of aldehydes was more useful, in that not all the hydroxy groups were blocked. Despite this, water solubility was a problem with the podophyllotoxin derivatives (**63**). Gastrointestinal absorption was greatly improved, however, as was chemical stability and positive effects were observed in a few cancer patients with the benzylidene derivative (**64**). It was at this point that luck played a hand, backed up by a good deal of determination. A crude podophyllin fraction that was simpler and cheaper to prepare than pure podophyllin glucoside, was also treated with benzaldehyde to give a mixture of benzylidene derivatives, about 80% of which was compound (**64**). The crude product was found to be more potent than compound (**64**) alone and subsequently, to possess a different mode of action from that of the lead



(**61**) R = CH_3
(**62**) R = H

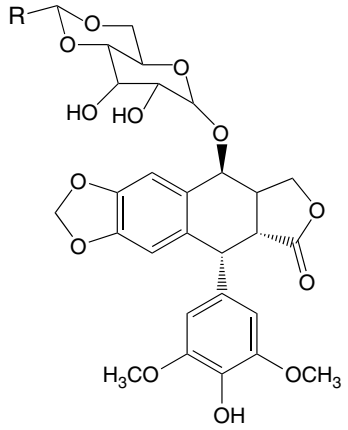


(**63**) R_1 = H, CH_3 R_2 = various alkyl, aryl
(**64**) R_1 = CH_3 R_2 = C_6H_5

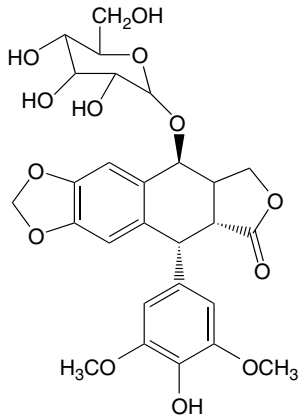
compounds: rather than arresting cells in metaphase, cells were prevented from entering mitosis altogether. The crude mixture was marketed for cancer treatment as *Proresid*.

Improved biological assay methods indicated the presence of an unknown, highly active constituent of Proresid. For example, Proresid prolonged the life of mice inoculated with L1210 leukemia cells, an effect that was not observed with the known major constituent. In the early 1960s, chromatographic and spectroscopic techniques were not as highly developed as they are now and more than 2 years of work was required to isolate and identify the unknown component of the mixture, which proved to be the 4′-desmethoxy-1-epi analog (**65**) of the podophyllotoxin glucoside adduct. Present only in very small amounts in the derivatized extract, it was necessary to devise a synthesis from readily available materials. It was fortunate that the desired 1β configuration was readily secured from 1α-hydroxy-4′-desmethylpodophyllotoxin, itself obtained by selective demethylation of podophyllotoxin: the remainder of the synthesis would now be considered routine.

Given a large supply of the key intermediate (**66**), it was straightforward to prepare a number of aldehyde derivatives, resulting in analogs with up to a 1000-fold increase in potency. The selected adducts were those prepared from thiophen-2-aldehyde, giving teniposide (**67**) and from acetaldehyde, giving etoposide (**68**). Both drugs are of value, etoposide in the treatment of small cell lung cancer and testicular cancer, teniposide in the treatment of lymphomas and leukemias. The thiophene derivative is also of use in the treatment of brain tumors.



(**65**) R = C_6H_5
(**67**) R = 2-thienyl
(**68**) R = CH_3



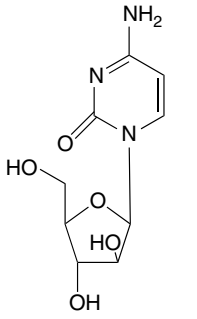
(**66**)

The natural products, podophyllotoxin and its congeners, are ''spindle poisons'' that inhibit cell proliferation by binding to tubulin and preventing formation of microtubules. Presumably, this effect is sufficient to account for the success of podophyllin in the treatment of condylomata acuminata, although the crude extract contains many other candidates for contribution to the biological activity. As

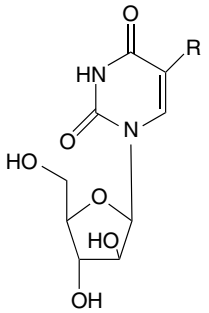
has been described, a very minor component of the natural mixture, missing the 4′-hydroxy group, having the 1β- instead of the 1α-hydroxy configuration and with this hydroxy group conjugated with β-D-glucose, must be treated with an aldehyde to produce the highly active and most important derivatives. These derivatives do not bind to tubulin, but have been shown to be inhibitors of topoisomerase II, which may account for most of the observed biological effects, including DNA strand breaks that lead to anticancer activity.

4.6 Marine Sources

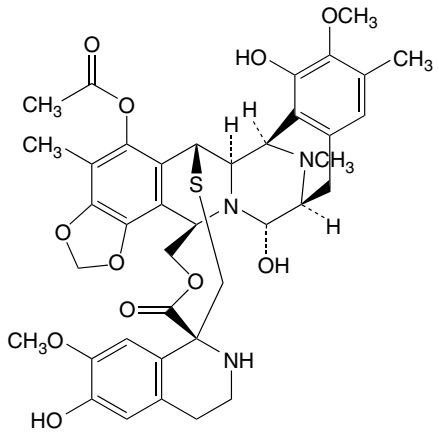
Cytosine arabinoside (**69**), a synthetic analog of the C-nucleosides spongouridine (**70**) and spongothymidine (**71**) from the sea sponge *Cryptotheca cripta*, was the first and, so far, the only marine-derived compound used routinely as an anticancer agent. However, a number of chemically diverse natural products from marine sources have been progressed to clinical trials. Some of the most advanced compounds include trabectedin (ecteinascidin-743) (**72**), a tetrahydroisoquinoline alkaloid isolated from the mangrove ascidian *Ecteinascidia turbinata*, bryostatin-1 (**73**), a macrolide isolated from the bryozoan *Bugula neritina*, and dolastatin-10 (**74**), a linear peptide from the sea mollusk *Dolabella auricularia*. Trabectedin (**72**) was first isolated by Rinehart's group at the University of Illinois and has been progressed recently to phase III clinical trials by PharmaMar (Zeltia) for the treatment of ovarian cancer.



(**69**) Cytosine arabinoside

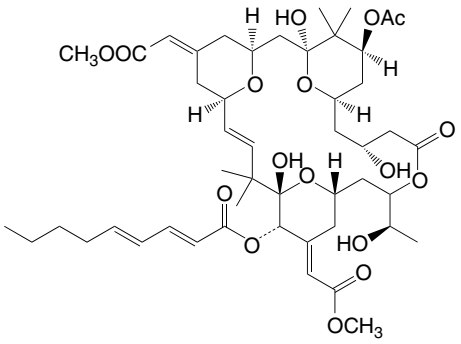


(**70**) Spongouridine: R = H
(**71**) Spongothymidine: R = CH_3



(**72**) Ecteinascidin-743

Yields of marine-derived natural products are invariably low and supply problems have delayed their development as useful pharmaceutical agents. For example, over 3000 kg of the sea squirt



(**73**) Bryostatin-1

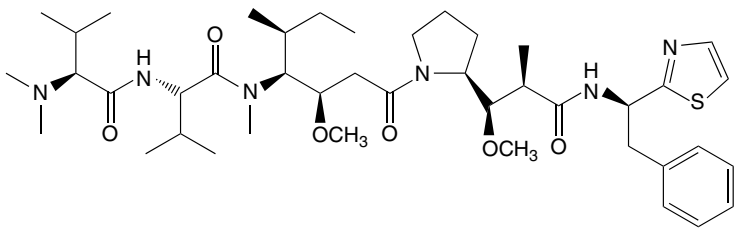
E. turbinata is required to produce 3 g of trabectedin (**72**), which is sufficient for just one cycle of treatment and 1000 kg of *B. neritina* yields 1.5 g of bryostatin-1 (**73**). Fortunately, supplies of trabectedin (**72**) have been met by semisynthesis and viable synthetic routes are now also available for bryostatin-1 (**73**) and dolastatin-10 (**74**).

5 Antibiotics

5.1 β-Lactams

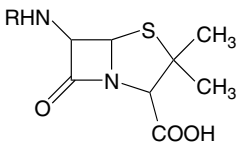
In 1929, Alexander Fleming published the results of his chance finding that a penicillium mold caused lysis of staphylococcal colonies on an agar plate. He also showed that the culture filtrate, named *penicillin*, possessed activity against important pathogens including gram-positive bacteria and gram-negative cocci. However, it was not until 1940 that the true therapeutic efficacy of penicillin was revealed, when Chain et al. successfully tested the material in mice that had been previously infected with a lethal dose of streptococci. Several years later, the precise chemical structure of the main active component, benzylpenicillin (**75**), was determined and efforts to synthesize the compound were initiated. Benzylpenicillin proved to be an elusive target because of the instability of the β-lactam ring: it was unstable under acid conditions and was deactivated by β-lactamase enzymes produced by various gram-positive and gram-negative bacteria.

The discovery that the fused β-lactam nucleus, 6-aminopenicillanic acid (6-APA) (**76**), could be obtained from cultures of *Penicillium chrysogenum* led to the preparation of new, semisynthetic derivatives with improved stability to gastric acid and β-lactamases and with activity against a wider range of pathogenic organisms. Sheehan showed that compound (**76**) would react readily with acid chlorides to form new penicillin derivatives with novel substituents at the 6-position. Methicillin (**77**), with a sterically demanding 2,6-dimethoxybenzamide side chain, was the first semisynthetic penicillin to show resistance to staphylococcal β-lactamases, although the compound was

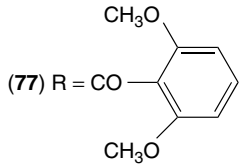


(**74**) Dolastatin-10

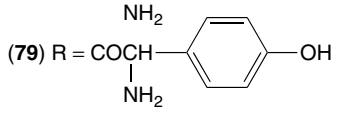
still acid labile. Ampicillin (**78**) has an α-aminophenylacetamido side chain and displays good activity against gram-negative organisms, it is stable to acid and thus can be administered orally, although it is susceptible to degradation by β-lactamases. Amoxycillin (**79**) differs from ampicillin by the addition of a single hydroxy group, but the compound is better absorbed by the gastrointestinal tract.

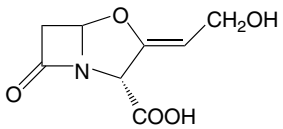


(**75**) R = $COCH_2Ph$
(**76**) R = H



(**78**) R = COCHPh
NH_2

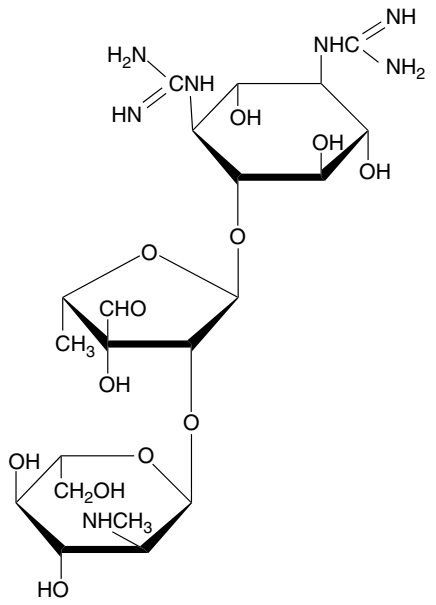




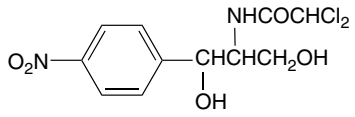
(**80**)

Clavulanic acid (**80**), isolated from *Streptomyces clavuligerus*, is similar in structure to the penicillins, except that oxygen replaces sulfur in the five-membered ring. Clavulanic acid has weak antibacterial activity, but is a potent inhibitor of β-lactamases. A mixture of clavulanic acid and the β-lactamase–sensitive amoxycillin was introduced in 1981 as Augmentin and has proved to be an effective combination to combat β-lactamase–producing bacteria. In 2001, 20 years after its launch, Augmentin was the best-selling antibacterial worldwide.

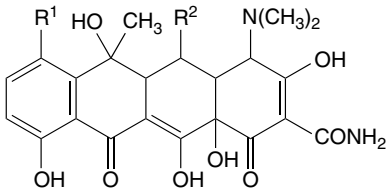
The clinical introduction of the penicillin group of antibiotics prompted an intensive search for novel antibiotic-producing organisms and Selman Waksman demonstrated the value of actinomycetes in this role, discovering the aminoglycoside streptomycin (**81**) from *Streptomyces griseus* in 1943. Pharmaceutical companies also embarked on large programs of screening soil samples for antibiotic-producing microorganisms. Chloramphenicol (**82**) was isolated from *Streptomyces venezuelae* in 1948 and other clinically important antibiotics followed: chlortetracycline (**83**), neomycin (**84**), oxytetracycline (**85**), erythromycin (**86**), oleandomycin (**87**), kanamycin (**88**), and rifamycin (**89**).



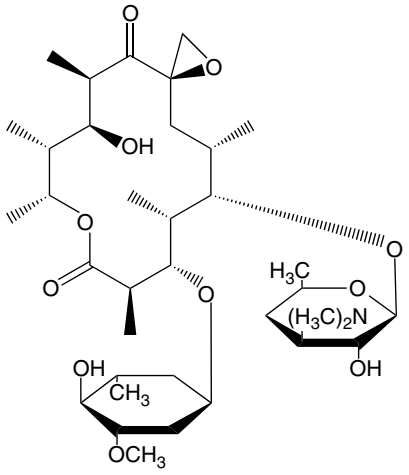
(**81**)



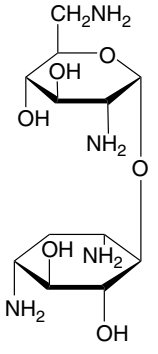
(**82**)



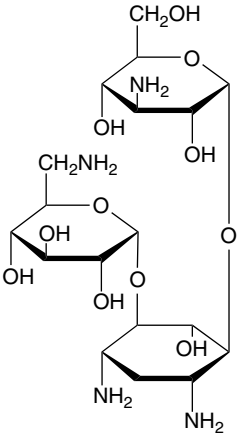
(**83**) R^1 = –Cl, R^2 = –H
(**85**) R^1 = –H, R^2 = –OH



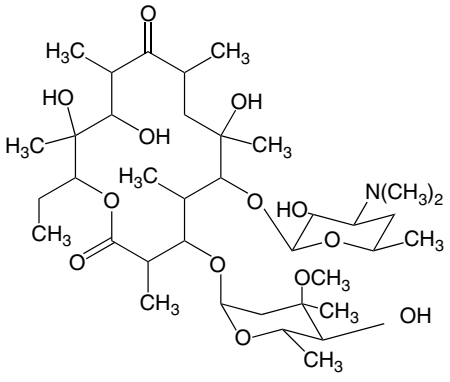
(**87**)



(**84**)

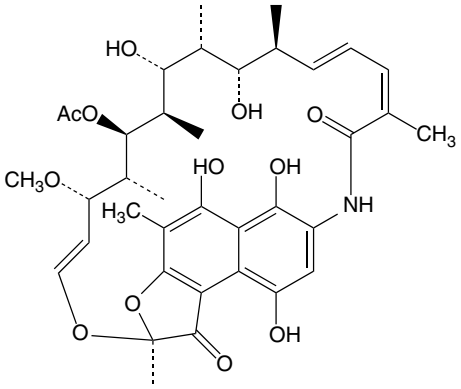


(**88**)

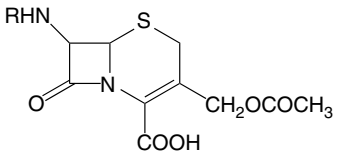


(**86**)

In 1948, Giuseppe Brotzu isolated the fungus *Cephalosporium acremonium* from a water sample collected off the coast of Sardinia. The culture showed significant antimicrobial activity, but Brotzu could not interest the Italian authorities in his discovery. He then turned to a friend in England for help, who arranged for Howard Florey at Oxford to receive a sample of the producing culture. Eventually,



(**89**)



(**90**) R = $COCH_2CH_2CH_2CHNH_2$ (COOH)

(**91**) R = H

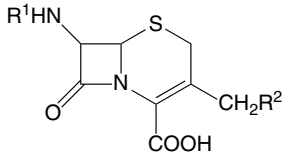
(**92**) R = $COCH_2$ 
(**93**) R = $COCH_2CN$

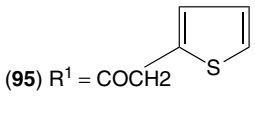
(**94**) R = $COCH_2S$ 
an antibacterial substance was isolated and named *cephalosporin C* (**90**). The compound, which had a structure similar to that of the penicillins, except that it had a dihydrothiazine ring fused to the β-lactam core, showed good resistance to β-lactamases and was less toxic than benzylpenicillin. However, plans to market the compound were terminated with the introduction of methicillin (mentioned earlier).

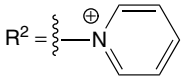
The discovery that the basic structural building block of cephalosporin C, that is, 7-aminocephalosporanic acid (7-ACA) (**91**), could be synthesized leading to the preparation of numerous cephalosporin derivatives in a similar way to the synthesis of penicillins from 6-aminopenicillanic acid. Modification of the substituent at the 7-position, while retaining the 3-acetoxymethyl group gave cephalothin (**92**), cephacetrile (**93**), and cephapirin (**94**), so-called first-generation cephalosporins with good activity against gram-positive bacteria, although the acetyl ester was susceptible to degradation by esterases and thus, limited the duration of action. Replacement of the acetoxy group by other substituents rendered the products less prone to esterase attack. For example, the pyridinium derivative, cephaloridine (**95**), has a longer duration of action than that of cephalothin.

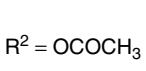
The first orally active cephalosporin was cephaloglycin (**96**), which possessed a phenylglycine substituent in the C-7 side chain, although the labile 3-acetoxymethyl group was retained. Replacing the acetoxy group with a proton or chlorine, for example, cephalexin (**97**), cefadroxil (**98**), cephradine (**99**), and cefaclor (**100**), extended the duration of action of these orally active products. Cefaclor has been classified as a second-generation cephalosporin because it has a wider spectrum of activity, which includes gram-negative bacteria such as *Haemophilus influenzae*. Cephamandole (**101**) and cefuroxime (**102**) are parenterally administered cephalosporins with similar activities against clinically important gram-negative bacteria and are also resistant to many types of β-lactamases.

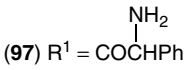
The newer third-generation cephalosporins, including ceftazidime (**103**), ceftizoxime (**104**), and ceftriaxone (**105**), which all contain an α-aminothiazolyl group in the C-7 side chain, have been developed for

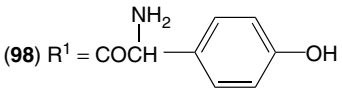


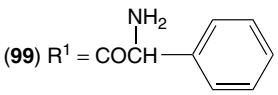




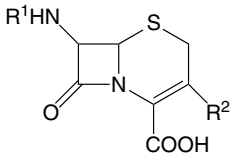


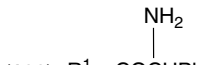


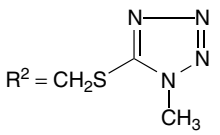


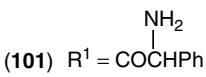


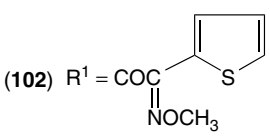
treating specific pathogens such as *Pseudomonas aeruginosa*. Thienamycin (**106**), isolated from *Streptomyces cattleya* in 1976, represented a new class of β-lactam antibiotics produced by bacteria where the sulfur of the penicillin nucleus was replaced by a methylene group. An *N*-formylimidoyl derivative, imipenem (**107**),

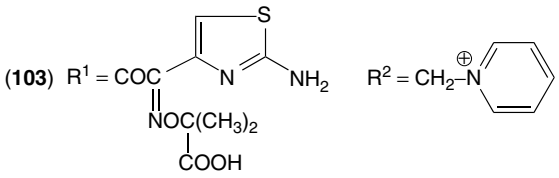


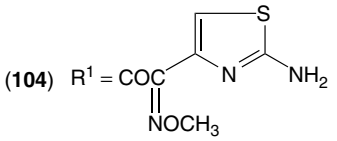


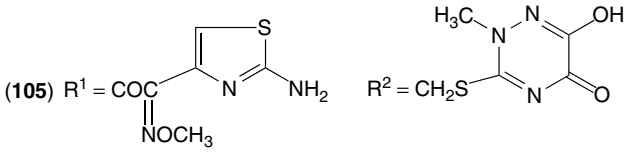




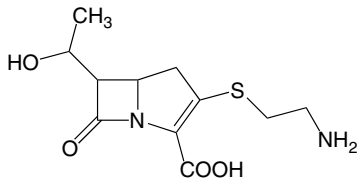




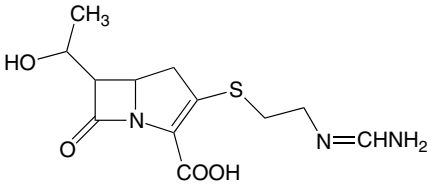




was the first example from this new class of carbapenem antibiotics to become available for clinical use. Imipenem has a very broad spectrum of activity against most gram-positive and gram-negative aerobic and anaerobic bacteria.

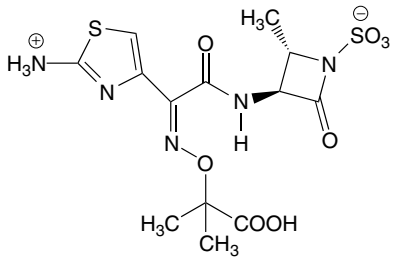


(**106**)



(**107**)

Screening bacteria such as *Pseudomonas acidophila* and *Chromobacterium violacium* for production of β-lactam antibiotics resulted in the discovery of naturally occurring monobactams, which had moderate antimicrobial activity. Side-chain variations, as developed for the penicillins and cephalosporins, led to compounds with improved activity against both gram-positive and gram-negative bacteria. A derivative containing the α-aminothiazolyl group, a side-chain component common to the third-generation cephalosporins (mentioned earlier), showed specific activity against gram-negative aerobic bacteria, including *Pseudomonas* spp. and was stable to most types of β-lactamases. The compound aztreonam (**108**) became the first

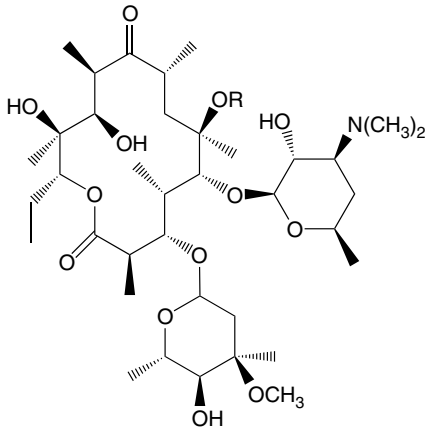


(**108**)

commercially available monobactam and showed a mode of action similar to that of the other β-lactam antibiotics by blocking bacterial cell wall synthesis.

5.2 Erythromycin Macrolides

Erythromycin (**109**) was isolated, in 1952, from a strain of *Saccharopolyspora erythraea* (formerly *Streptomyces erythreus*). As a broad-spectrum antibiotic, erythromycin has proved invaluable for the treatment of bacterial infections in patients with β-lactam hypersensitivity and is also the drug of choice in the treatment of infections caused by species of *Legionella, Mycoplasma, Campylobacter*, and *Bordetella*.

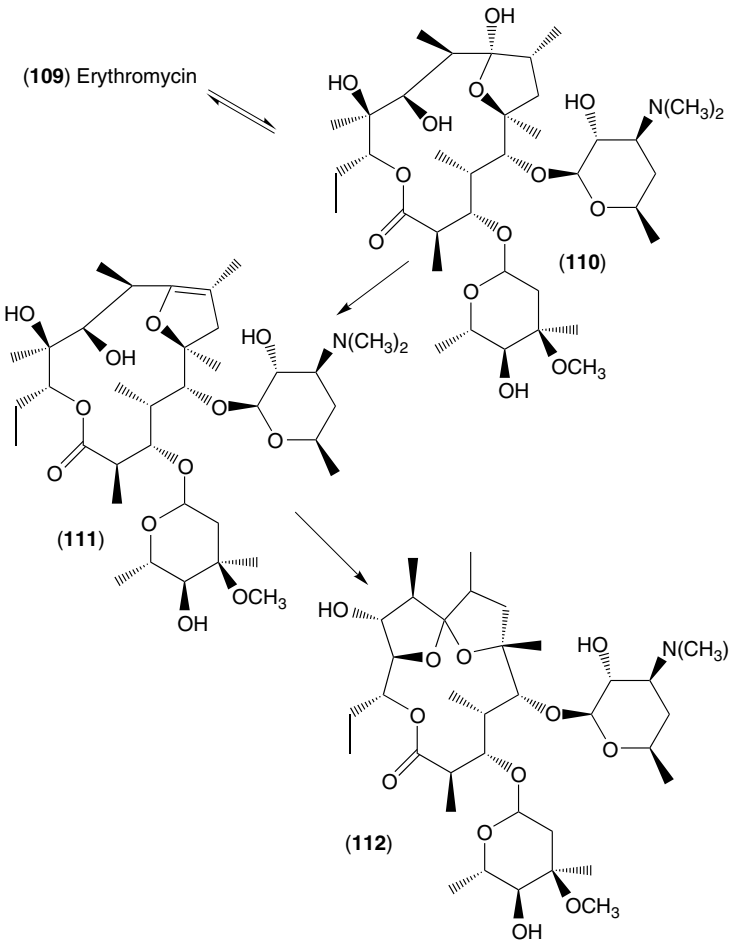


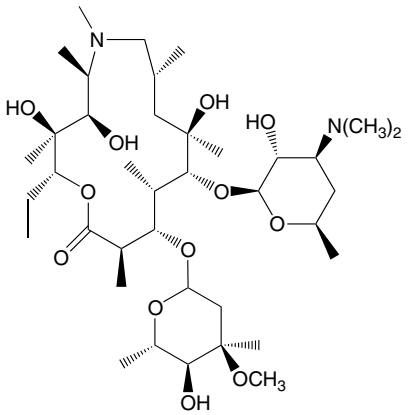
(**109**) Erythromycin A, R = H
(**114**) Clarithromycin, R = CH_3

Although safe and effective, erythromycin is not a perfect antibacterial. The presence of hydroxy groups suitably disposed with respect to the keto function at C-9 leads to the formation of a tautomeric mixture of hemiketals. The 6,9-hemiketal (**110**) may be dehydrated in stomach acid to give the inactive δ_8 analog (**111**), which can undergo further ring closure to give the 9,12-tetrahydrofuran (**112**) that is also inactive. The δ_8 derivative (**111**) may be responsible for some gastrointestinal disturbance. To avoid these problems by increasing the stability to acid, the 2′-stearate, estolate, and ethylsuccinate esters have been prepared, but even when the tablets are enteric-coated the bioavailability is erratic and relatively frequent dosing is required.

An understanding of the acid-catalyzed decomposition of erythromycin has led to a variety of semisynthetic derivatives with improved oral bioavailability. Reductive amination of the 9-keto function gives erythromycylamine, which reacts with (2-methoxyethoxy) acetaldehyde to give dithromycin. Beckmann rearrangement of the 9-oxime followed by reduction and methylation gives azithromycin (**113**), which shows good activity against gram-negative bacteria, including *H. influenzae*. An alternative for prevention of cyclization between the 9-keto and 6-hydroxy is to mask the 6-hydroxy group. If the 6-hydroxy is methylated, the result is clarithromycin (**114**), which like (**113**), has an improved pharmacokinetic profile compared with that of the parent molecule.

Both azithromycin and clarithromycin have been used for various bacterial infections for a number of years. Within the last decade, resistance has emerged to a range of antibacterials, including the macrolides, arising from methylation of an adenine in the 23S ribosomal RNA target site, which prevents binding. However, the ketolides (e.g. telithromycin (**115**)) overcome MLS_B resistance because they lack the L-cladinose moiety at position 3: the exposed hydroxyl is also oxidized to a ketone. The loss of potency, which would ensue, is compensated by two further modifications that improve binding; formation of



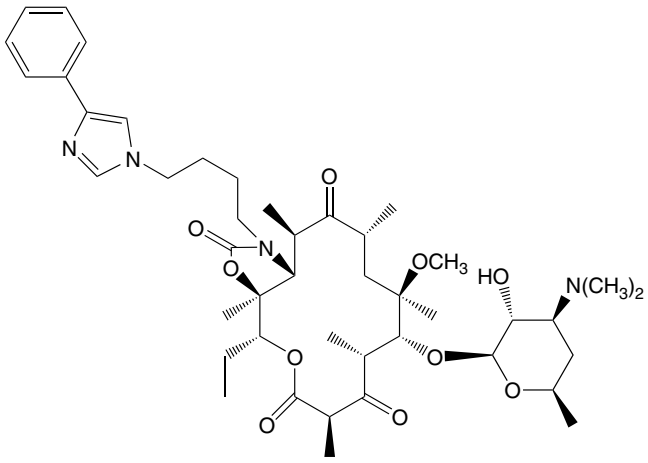


(113) Azithromycin

a carbamate at positions 11/12 and extension with a heterocycle-substituted side chain. In ABT 773 a similar side chain is placed at position 6 with comparable results.

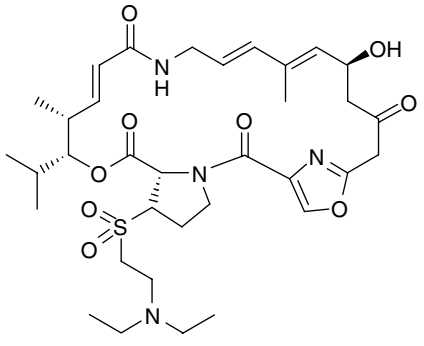
5.3 Streptogramins

The streptogramins are produced by *Streptomyces* species and have been classified into two groups: Group A are polyunsaturated macrocyclic lactones and Group B are cyclic hexadepsipeptides. Both groups



(**115**) Telithromycin

bind bacterial ribosomes, inhibit protein synthesis at the elongation step, and act synergistically against many gram-positive microorganisms. However, the naturally occurring streptogramins are poorly soluble in water and this, until recently, has limited their use for treating bacterial infections. New, water-soluble derivatives have been developed and the semisynthetic dalfopristin (**116**) and quinupristin (**117**) mixture (Synercid) has been approved for the treatment of gram-positive infections, including multidrug-resistant strains of *Enterococcus faecium*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*.

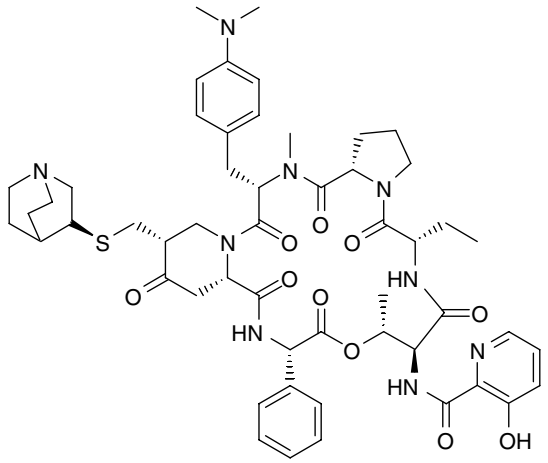


(**116**) Dalfopristin

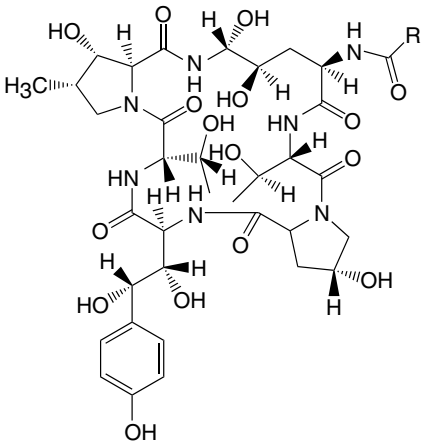
5.4 Echinocandins

The fungal metabolite echinocandin B (**118**) is one of the lipopeptides in which a cyclic hexapeptide is combined with a long-chain fatty acid. Echinocandin B inhibits β-1,3-glucan synthesis and as a result has anti-Candida and anti-*Pneumocystis carinii* activity. As a group, the echinocandins are not orally bioavailable, are hemolytic, and are not very water soluble, despite the hydrogen-bonding ability of the polyhydroxylated hexapeptide.

Synthesis of the cyclic hexapeptide is unattractive for the purpose of securing analogs with improved biological activity because of the unusual nature of the amino acids used and the complex stereochemistry generated by the high degree of hydroxylation. However, echinocandin B can be produced efficiently by fermentation of *Aspergillus nidulans*



(**117**) Quinupristin



(**118**) Echinocandin B, R = linoleyl

(**119**) Cilofungin, R = 
into problems associated with the cosolvent polyethylene glycol. A better derivative, anidulafungin (LY-303366) (**120**) has the major advantage of oral bioavailability and has been progressed to phase III clinical trials. Many other antifungal peptides are under investigation and two members of this series have now been marketed, caspofungin (MK-991, L-743,872) (**121**) and micafungin (FK463), for the treatment of aspergillosis and candidiasis.

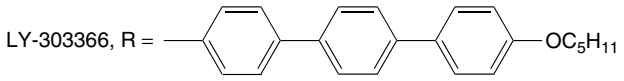
and then deacylated by fermentation with *Actinoplanes utahensis*. The free amino group thus exposed can be derivatized with a number of active esters. Synthesis of the amide from 4-octylbenzoic acid gives cilofungin (**119**), which has specifically high potency against *Candida albicans* and some other Candida species.

For systemic use, cilofungin had to be given intravenously and unfortunately, ran

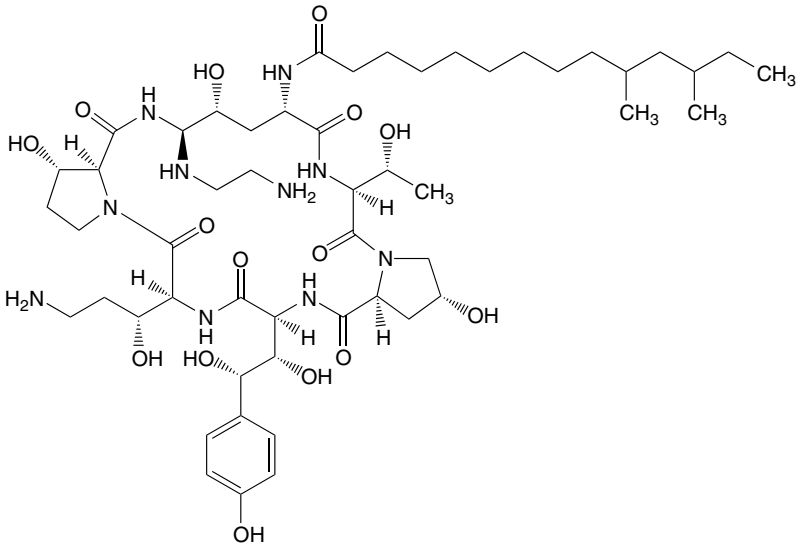
6
Cardiovascular Drugs

6.1
Lovastatin, Simvastatin, and Pravastatin

One of the most significant natural product discoveries in the last 30 years has been a fungal secondary metabolite called *lovastatin* (**122**). Heralded as a major



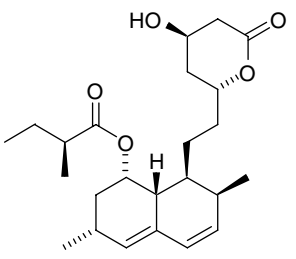
(**120**)



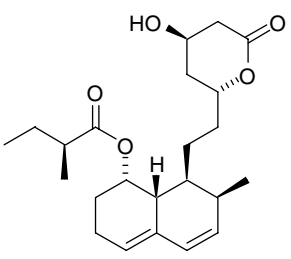
(**121**) Caspofungin

breakthrough in the treatment of coronary heart disease, lovastatin was introduced onto the market by Merck in 1987 for the treatment of hypercholesterolemia, a condition marked by elevated levels of cholesterol in the blood.

Lovastatin works by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, a key rate-limiting enzyme in the cholesterol biosynthetic pathway. However, the first specific inhibitors of this enzyme were discovered several years earlier by Endo et al. at Sankyo. The compounds, which are structurally related to lovastatin, were isolated from *Penicillium citrinum* and shown to block cholesterol synthesis in rats and lower cholesterol levels in the blood. Development of the most active compound, designated ML-236B (**123**), is believed to have been curtailed because of toxicity problems.



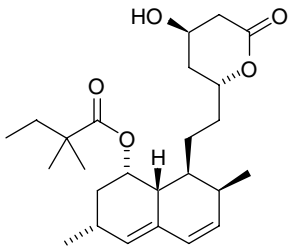
(**122**)



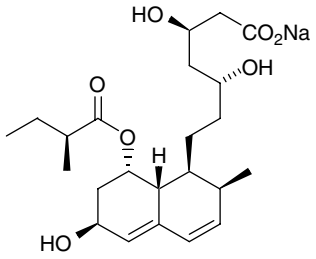
(**123**)

Brown et al. at Beechams also reported the isolation of (**123**), but as a metabolite from *Penicillium brevicompactum*. The group, naming the compound compactin, reported its antifungal activity but failed to reveal its mode of action as an inhibitor of HMG-CoA reductase. The search for naturally occurring inhibitors of HMG-CoA reductase gained pace and after spending several years developing appropriate screens, Merck found during only the second week of testing, a culture of *Aspergillus terreus* that displayed interesting inhibitory activity. In February 1979, the active component, lovastatin (mevinolin), was isolated and characterized, and in November the following year Merck was granted patent protection in the United States. Although lovastatin proved to be identical to monocolin K, a metabolite isolated earlier from *Monascus ruber*, the chemical structure of the latter compound had not been reported, whereas Merck filed for patent protection giving complete structural details for lovastatin.

The discovery of compactin and lovastatin prompted efforts to develop derivatives with improved biological properties. Modification of the methylbutyryl side chain of lovastatin led to a series of new ester derivatives with varying potency and, in particular, introduction of an additional methyl group α to the carbonyl gave a compound with 2.5 times the intrinsic enzyme activity of lovastatin. The new derivative, named *simvastatin* (**124**), was the second HMG-CoA reductase inhibitor to be marketed by Merck. Both lovastatin and simvastatin are prodrugs and are hydrolyzed to their active open-chain dihydroxy acid forms in the liver. A third compound, pravastatin (**125**), launched by Sankyo and Squibb in 1989, is the open hydroxyacid form of compactin that was first identified as a urinary metabolite in dogs. Pravastatin is produced by microbial biotransformation of compactin.

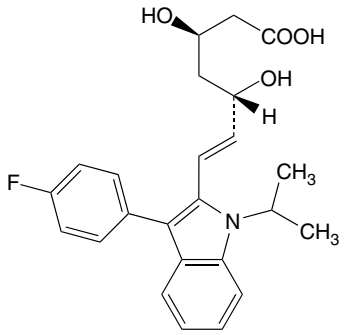


(**124**)

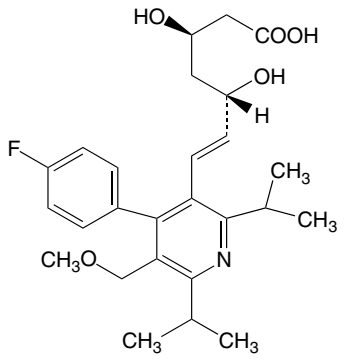


(**125**)

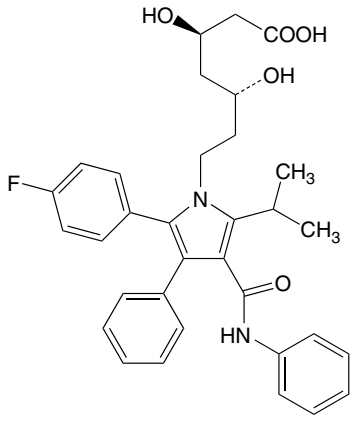
The HMG-CoA reductase inhibitors described earlier bind to two active sites on the enzyme: the hydroxymethylglutaryl binding domain and an adjacent hydrophobic pocket to which the decalin moiety binds. The recognition that the ring-opened hydroxy acids resemble mevalonic acid and that the decalin moiety could be replaced by 4-fluorophenyl–substituted heterocycles led to the launch of several new products including fluvastatin (**126**), the ill-fated cerivastatin (**127**) and the so-called turbostatin atorvastatin (**128**). Although cerivastatin was withdrawn from the market in 2001 because of fatal adverse drug–drug interactions, the ''statins'' remain one of the fastest growing



(**126**) Fluvastatin

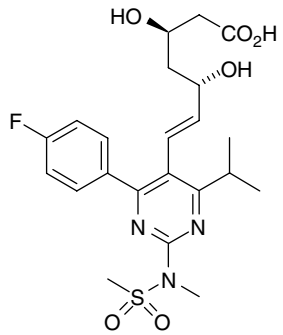


(**127**) Cerivastatin



(**128**) Atorvastatin

segments of the pharmaceutical industry. One of the latest members of this group of cholesterol-lowering drugs to be marketed is AstraZeneca's rosuvastatin (**129**).



(**129**) Rosuvastatin

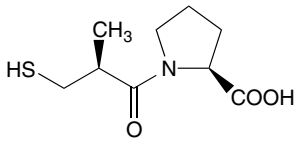
6.2
Teprotide and Captopril

While studying the physiological effects of snake poisoning, Ferreira discovered that specific components in the venom of the pit viper *Bothrops jararaca* inhibited degradation of the peptide bradykinin and potentiated its hypotensive action. The "potentiating factors" proved to be a family of peptides that worked by inhibiting the dipeptidyl carboxypeptidase, angiotensin-converting enzyme (ACE). In addition to catalyzing the degradation of bradykinin, ACE also catalyzes the conversion of human prohormone, angiotensin 1, to the potent vasoconstrictor octapeptide, angiotensin II. However, the significance of ACE in the pathogenesis of hypertension was not fully appreciated until the 1970s after Ondetti et al. had first isolated and then synthesized the naturally occurring nonapeptide, teprotide (**130**). The compound proved to be a specific potent inhibitor of ACE and showed excellent antihypertensive properties in clinical trials, although

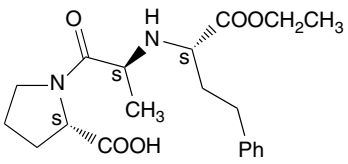
its use was limited by the lack of oral activity.

Pyr–Trp–Pro–Arg–Pro–Gln–Ile–Pro–Pro
(**130**)

The discovery of teprotide led to a search for new, specific, orally active ACE inhibitors. Ondetti et al. proposed a hypothetical model of the active site of ACE, based on analogy with pancreatic carboxypeptidase A and used it to predict and design compounds that would occupy the carboxy-terminal binding site of the enzyme. Carboxyalkanoyl and mercaptoalkanoyl derivatives of proline were found to act as potent, specific inhibitors of ACE and 2-D-methyl-3-mercaptopropanoyl-L-proline (**131**) (captopril) was developed and launched in 1981 as an orally active treatment for patients with severe or advanced hypertension. Captopril, modeled on the biologically active peptides found in the venom of the pit viper, made an important contribution to the understanding of hypertension and paved the way for other ACE inhibitors, such as enalapril (**132**) and lisinopril, which have had a major impact on the treatment of cardiovascular disease.



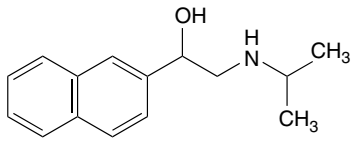
(**131**)



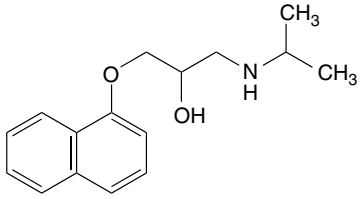
(**132**)

6.3
Adrenaline, Propranolol, and Atenolol

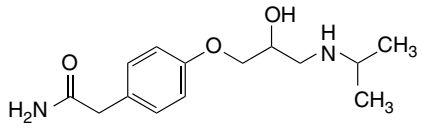
The true clinical potential of β-adrenoceptor blocking agents for treating angina, atrial fibrillation, and tachycardias was first recognized by James Black and colleagues at ICI. Black noted a report from Neil Moran of Emory University in 1958, showing that dichloroisoprenaline antagonized the effects of adrenaline on heart rate and muscle tension. The first effective β-adrenoceptor blocker, pronethalol (**133**), was synthesized 2 years later by the ICI group and marketed for limited use in 1963. Toxicity problems soon led pronethalol to be replaced by the 1-naphthyl analog, propranolol (**134**), which became the first β-adrenoceptor antagonist approved for general use, being more potent and yet devoid of the partial agonist or intrinsic sympathomimetic activity shown by many other analogs. Compounds with improved selectivity for the β-adrenoceptor of cardiac muscle (β-1-adrenoceptor blockers) were to follow, including atenolol (**135**), which became the most frequently prescribed beta-blocker and one of the best-selling drugs of the time.



(**133**) Pronethalol



(**134**) Propranolol

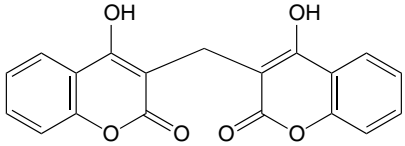


(**135**) Atenolol

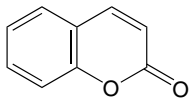
6.4 Dicoumarol and Warfarin

Sweet clover has a long history of medicinal use, often as an antiflammatory or analgesic preparation in the form of ointments and poultices. *Melilotus officinalis* (yellow sweet clover, or ribbed melilot) was reputed to have been a favorite herbal treatment used by King Henry VIII of England and the plant is still referred to as *King's Clover* in some publications.

The plant flourishes in poor soil and was cultivated extensively in Europe for cattle fodder and for soil improvement. In the early 1920s, *M. officinalis* was planted on the prairies of North Dakota and Alberta, Canada, but with disastrous consequences. Soon cattle and sheep throughout these regions began literally bleeding to death. The mysterious hemorrhagic disease was traced to clover fodder that had not been stored properly and had become "spoiled," or moldy. However, the insolubility of the anticoagulant component and the difficulty of assaying extracts for biological activity made the task of isolating the active principal component intractable. It took almost 20 years before the compound was identified as 3,3′-methylenebis(4-hydroxycoumarin) (**136**), an oxidative degradation metabolite of coumarin (**137**), itself a common component of *Melilotus* sp. Soon after the compound had been identified, trials were initiated that confirmed the oral anticoagulant activity in humans and in 1942, it was marketed under the name dicoumarol. The compound had a slow, erratic onset of action and efforts were initiated to prepare synthetic analogs that acted faster and had longer duration of action. A 4-hydroxycoumarin residue, substituted at the 3-position, proved essential for biological activity and in 1948, after synthesizing over 150 compounds, a 4-hydroxycoumarin derivative that was longer acting and more potent than dicoumarol was selected not for clinical use, but as a rodenticide for development by the Wisconsin Alumni Research Foundation! The compound (**138**), named *warfarin* (an acronym derived from the name of the institute coupled with "arin" from coumarin), became a household name for rat poison. Concern over the use of oral anticoagulants and the inherent risk of hemorrhage inhibited the development of warfarin as a therapeutic agent. However, in 1951, a US Army cadet unsuccessfully attempted to commit suicide by taking massive doses of the compound. The incident prompted further clinical trials that resulted in warfarin being used as the anticoagulant of choice for prevention of thromboembolic disease.

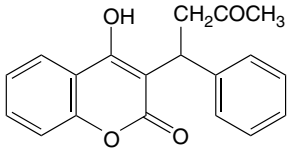


(**136**)



(**137**)

The mode of action of the coumarin anticoagulants involves blocking the regeneration of reduced vitamin K and induces a state of functional vitamin K



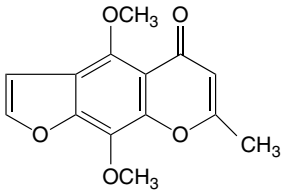
(**138**)

deficiency, thus interfering with the blood-clotting mechanism.

7
Antiasthma Drugs

7.1
Khellin and Sodium Cromoglycate

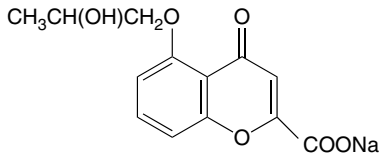
The toothpick plant, *Ammi visnaga*, had been used for centuries in Egypt as an antispasmodic agent to treat renal colic and ureteral spasm. In 1879, one of the plant's main constituents was isolated, crystallized, and named *khellin* (**139**). Subsequently, the pure compound was shown to relax smooth muscle and in 1938, the chemical structure was characterized as a chromone derivative. In 1945, a medical technician took khellin to treat renal colic and found instead that it acted as a potent coronary vasodilator and relieved his angina. This chance discovery, together with earlier observations, led to khellin being used as a coronary artery vasodilator and for treating bronchial asthma. However, its clinical use was severely limited by some unpleasant gastrointestinal side effects.



(**139**)

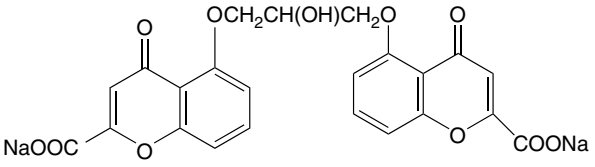
Five years later, a small British pharmaceutical company, called *Benger Laboratories*, initiated a program to synthesize khellin analogs as potential bronchodilators for treating asthma and had prepared a series of compounds that relaxed guinea pig bronchial smooth muscle and protected the animals against allergen-induced bronchospasm.

A clinical pharmacologist on Benger's staff, who suffered from chronic asthma, questioned the validity of the animal model and decided instead to test the compounds on himself. He then prepared a "soup" of guinea pig fur, inhaled the vapors to induce a reproducible asthma attack, and assessed the effects of the synthesized khellin derivatives. Many of the compounds first prepared were insoluble in water and caused nausea and other unpleasant side effects when taken orally. This led to the test compounds being formulated as aerosol sprays and in 1958, an aerosol preparation of a chromone-2-carboxylic acid derivative (**140**) was found to exert a protectant effect, albeit short lived, against bronchial allergen challenge without showing the bronchodilator activity seen with other compounds. The compound was completely inactive in the guinea pig asthma model and afforded its protectant effect in humans only when inhaled as an aerosol.

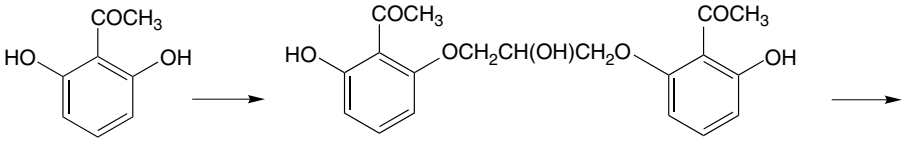


(**140**)

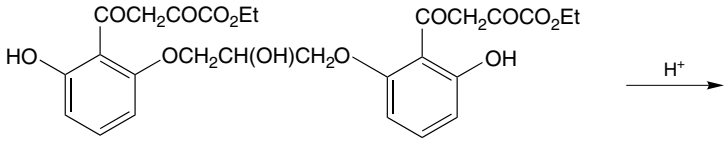
About two new compounds were tested each week and in 1965, after synthesizing



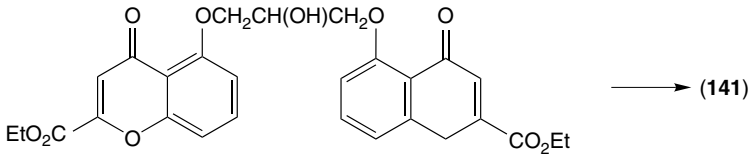
(**141**)



(**142**)



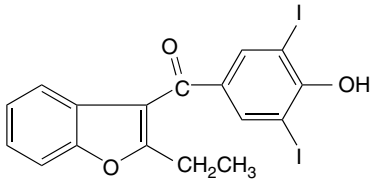
(**143**)



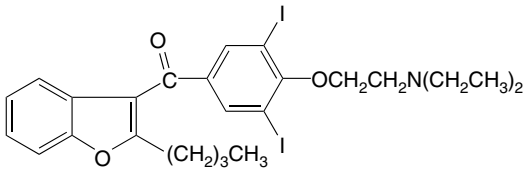
some 670 analogs, a bischromone was prepared that gave good protection, even when inhaled up to 6 h before bronchial allergen challenge. The compound sodium cromoglycate (**141**) was obtained by condensing diethyl oxalate with the bis(hydroxy acetophenone) (**142**) and cyclizing the resultant bis(2,4-dioxobutyric acid) ester (**143**) under acidic conditions. The essential chemical features required for activity appeared to be the coplanarity of the chromone nuclei, the flexible dioxyalkyl link and the carboxyl groups in the 2-positions. It is believed to act by stabilizing tissue mast cells against degranulation, thereby preventing release of inflammatory mediators.

Sodium cromoglycate entered clinical trials in 1967 and emerged to become a first-line prophylactic treatment for bronchial asthma.

The coronary dilator properties of khellin have not been ignored and at least one successful program was initiated to prepare analogs for testing as potential antiangina drugs. Benziodarone (**144**) was the first useful compound to emerge from the Labaz laboratories in Belgium based on the benzofuran ring system. However, the compound caused



(**144**) Benziodarone

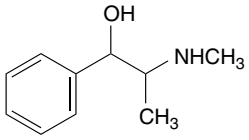


(**145**) Amiodarone

hepatotoxicity in man and was soon superseded by amiodarone (**145**), a more potent coronary dilator for treating angina. In 1970, the first report of antiarrhythmic activity in the clinic was published and amiodarone became established for prophylactic control of supraventricular and ventricular arrhythmias during the 1980s.

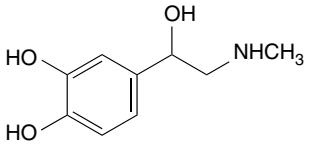
7.2 Ephedrine, Isoprenaline, and Salbutamol

The Chinese have been using a plant extract known as *ma huang* to treat asthma and hay fever for thousands of years. The extract is prepared from several species of *Ephedra*, a small leafless shrub found in China. Following experiments at the Peking Union Medical College and then at the University of Pennsylvania and the Mayo Clinic in the United States, the active ingredient, ephedrine (**146**), was introduced into Western medicine in 1926 as an orally active bronchodilator for the treatment of acute asthma.

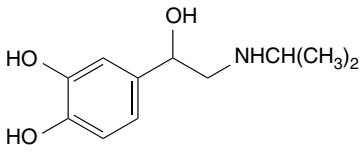


(**146**)

Ephedrine is related to another natural product that has been used to treat asthma, that is, the adrenal hormone adrenaline (**147**) (epinephrine). Adrenaline is a potent agonist of both α- and β-adrenoceptors and thus produces arterial hypertension as an undesirable side effect. In 1951, a synthetic alternative, isoprenaline (**148**), was



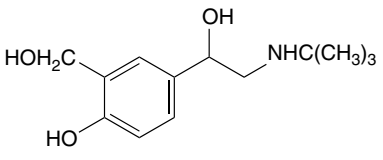
(**147**)



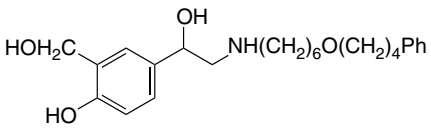
(**148**)

introduced and for almost 20 years it was considered the drug of choice for treating bronchospasm associated with acute asthmatic attack. Isoprenaline is a specific β-adrenoceptor agonist and, although it has no vasoconstrictor activity, the compound does have marked cardiac stimulant properties and a short duration of action. Ahlquist's concept of two types of adrenoceptor was developed further by Lands et al., who established the existence of β_1- and β_2-adrenoceptor subtypes. Clear structure–activity relationships emerged with the preparation of compounds related to adrenaline and ephedrine; the basic requirement for β-adrenoceptor agonist

activity was an aromatic ring substituted by an ethanolamine side chain. The branched methyl substituent on the side chain was associated with prolonged duration of action (i.e. ephedrine), whereas aromatic hydroxylation (in isoprenaline) prevented penetration across the blood–brain barrier and thus prevented stimulation of the CNS. However, 1,2-dihydroxy substituents were found to promote enzymic degradation, and replacement of the 3-hydroxy group by a hydroxymethyl substituent was required to extend the duration of action. In 1969, salbutamol (**149**) was launched by Glaxo as a longer-lasting, selective β_2-adrenoceptor agonist for the treatment of bronchial asthma and, subsequently, a lipophilic ether analog, salmeterol (**150**), was introduced with an even longer duration of action that has potential advantage in the prevention of nocturnal asthma.



(**149**)

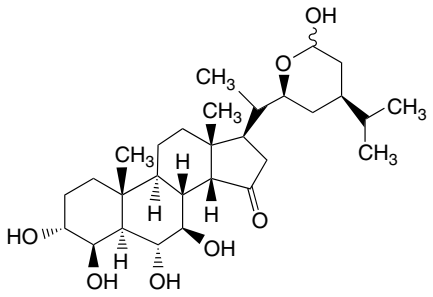


(**150**)

Despite the many chemical alterations that have been carried out on the phenylethanolamine "template," the key chemical features associated with modern β-agonists can be seen to have originated from the naturally occurring compounds, adrenaline and ephedrine.

7.3
Contignasterol

The use of inhaled corticosteroids such as fluticasone propionate to treat asthma and rhinitis has been well documented and will not be repeated here. Less well known is an unusual, highly oxygenated marine-derived steroid isolated from the sponge *Petrosia contignata* that possesses a unique cyclic hemiacyl side chain (**151**). The compound was isolated by Andersen and coworkers at the University of British Columbia and found to possess anti-inflammatory properties *in vivo*. Contignasterol was being developed by Inflazyme, in collaboration with Aventis, for the treatment of asthma and other inflammatory diseases and progressed to phase II clinical trials.



(**151**) Contignasterol

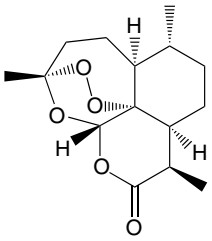
8
Antiparasitic Drugs

8.1
Artemisinin, Artemether, and Arteether

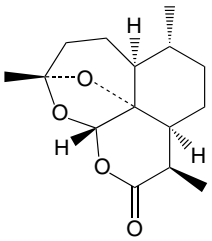
Artemisia annua (sweet wormwood, Qing hao) has been used in Chinese medicine for well over 1000 years. The earliest recommendation is for the treatment of hemorrhoids, but there is a written record of use in fevers dated 340 A.D. Modern

development dates from the isolation of a highly active antimalarial, artemisinin (qinghaosu), in 1972, and has been carried out almost entirely in China. Much of the original literature is therefore, in Chinese.

Artemisinin (**152**) is a sesquiterpene lactone with an unusual peroxide bridge. One of the earliest modifications involved catalytic reduction of the peroxide, resulting in loss of one oxygen and total loss of antimalarial activity in the adduct (**153**). The role of the peroxide bridge in producing antimalarial effects was not fully understood, but it appeared essential for activity, so much of the early work on analogs conserved this structural feature as an empirical finding. The mechanism of action of artemisinin has since been elucidated, although it is not without controversy. The drug has a high affinity for hemozoin, a storage form of hemin that is retained by the parasite after digestion of hemoglobin, leading to a highly selective accumulation of the drug by the parasite.



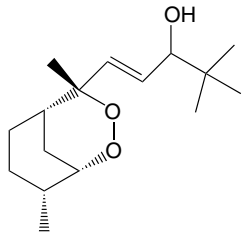
(**152**) Artemisinin



(**153**)

Artemisinin then decomposes in the presence of iron, probably from the hemozoin and releases free radicals, which kill the parasite. The peroxide bridge is, therefore, a crucial part of the drug molecule, as was suspected from structure–activity studies. Elucidation of the mechanism of action has led to the synthesis of a range of simple analogs capable of iron-catalyzed decomposition, some of which have good antimalarial activity.

In retrospect, it is not surprising that the peroxide-bridged compound (**154**), isolated from *Artabotrys uncinatus*, also has antimalarial activity. Because peroxides of this kind are likely to be formed from a variety of precursors in dried plant material (see the following), there may well be many more antimalarials of this kind to be found.

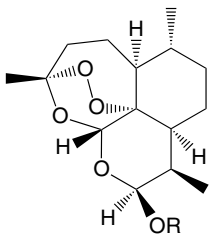


(**154**)

Artemisinin is an excellent antimalarial, approximately equal in potency to chloroquine, with a good therapeutic index except on the fetus. The preparation of semisynthetic derivatives has been stimulated primarily by a requirement for improved solubility because artemisinin is relatively insoluble in both water and oil.

Reduction of (**152**) with sodium borohydride occurs at the lactone carbonyl, leaving the peroxide intact. The resulting cyclic hemiacetal, dihydroartemisinin (**155**), which is a more potent antimalarial than the parent compound, shows typical acetal reactivity. In the presence of acid,

a highly reactive carbocation intermediate allows S_N1-type substitution with a variety of nucleophiles. For example, boron trifluoride catalyzes reactions with methanol and ethanol to give artemether (**156**) and arteether (**157**), respectively, two of the most important derivatives. Both are more potent than the parent compound and have improved solubility in oil. Artemether has been chosen for development under the name Paluther.



(**155**) R = H
(**156**) R = CH_3 artemether
(**157**) R = CH_2CH_3 arteether
(**158**) R = $COCH_2CH_2COONa$ sodium artesunate

Water solubility can be greatly improved by the standard ploy of esterification with succinic acid and conversion to the sodium salt. Applied to compound (**155**), this technique gives sodium artesunate (**158**), a water-soluble prodrug that may be given intravenously. It may be assumed that hydrolysis occurs *in vivo* to give back (**155**) as the active antimalarial because (**156**) has been shown to be unstable in aqueous solution and because analogous carboxylic acids with a nonhydrolyzable ether link are relatively inactive.

There are two reasons for the great interest being shown in artemisinin and its derivatives. First, there is little cross-resistance with *Plasmodium falciparum* between the members of this series and the quinoline-based antimalarials like chloroquine. On the contrary, significant potentiation of effect is observed in combination with chloroquine analogs such as mefloquine. Second, the high lipid solubility of, for example, artemether ensures rapid penetration into the CNS, so these sesquiterpene lactones are first-line drugs for the treatment of cerebral malaria caused by *P. falciparum*, which is otherwise fatal.

It seems likely that most of the artemisinin found in dried plant material is formed by autoxidation after the death of the plant. From the medicinal chemist's point of view, this is unimportant, but some plant biochemists might have doubts about the description of artemisinin as a "natural product." Air drying in sunlight may be considered a natural, although not a botanical, process. It is probable that many other plant-derived peroxides are formed in a similar way.

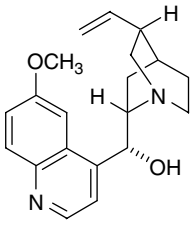
Whole plant extracts often show promising activity that may not be traceable to single components. This is obviously not true of *A. annua* extracts, but it is interesting to note that other constituents, notably methoxylated flavones, have potentiating effects on the antimalarial activity of artemisinin.

The reported effect of artemisinin on systemic lupus erythematosus is intriguing, given the history of use of quinine-type antimalarials in this disease.

8.2 Quinine, Chloroquine, and Mefloquine

The use of cinchona bark (e.g. *Cinchona succirubra*) by South American Indians to treat fevers and the subsequent importation of the bark into Europe by Jesuit priests in the seventeenth century is well known. At that time malaria was widespread, even as far north as eastern Scotland and there was no effective

treatment for ''the ague.'' Although quinine (**159**) is not very potent or long acting, a good sample of cinchona bark contains about 5% of the alkaloid. This high concentration permitted genuinely therapeutic doses of bark to be given and allowed the pure alkaloid to be isolated as early as 1820. During the next 100 years, quinine was the only effective treatment for malaria known to Europeans. Without quinine, life in the tropics was impossible for those without natural immunity to malaria. Supplies of quinine to Europe were threatened during World War I, stimulating a major program of research into synthetic analogs.

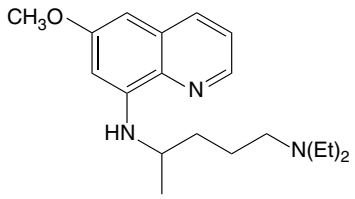


(**159**) Quinine

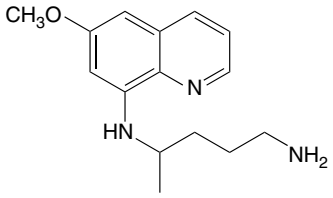
The chemical techniques available to chemists in the period 1820–1920, although improving rapidly, did not allow a structure to be proposed for quinine with any confidence: the first completely correct proposal came in 1922 and was finally confirmed by total synthesis as late as 1945. However, part structures were known, such as the 6-methoxyquinoline moiety and were sufficient to allow the synthesis of mimics. The first clinically successful mimics were the 8-aminoquinolines.

In the early years of the twentieth century, synthetic organic chemistry was a young discipline, largely governed by empirical rules. Progress toward synthetic analogs of complex natural structures was governed as much by synthetic feasibility as by a desire for close mimicry. The first quinine analogs were, therefore, a combination of the accessible 6-methoxyquinoline part of the quinine structure, with elements of the first successful antimicrobial agents, such as 9-aminoacridine. Nitration followed by reduction could be used to generate a number of new molecules from a variety of parent heterocycles. It is recorded that 4-, 6-, and 8-aminoquinolines have antimalarial properties and, quite extraordinarily, two of these chemical classes are still used today, have quite different uses as antimalarials, and quite possibly have different modes of action.

The first of the 8-aminoquinolines to be introduced into medicine was pamaquine (**160**), not long after World War I. Despite greater toxicity than that of quinine, this class of drugs was found to have radical curative ability against the relapsing malarias. Several hundred analogs were tested during World War II and of these, primaquine (**161**) survives to the present day for short-term use as a radical curative.

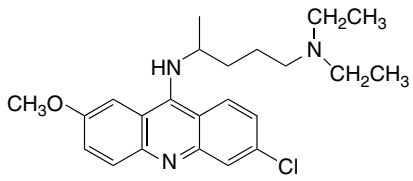


(**160**) Pamaquine



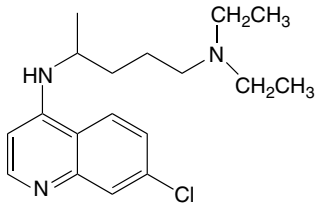
(**161**) Primaquine

Quinacrine (**162**) is an obvious embodiment of the principle outlined above; as a derivative of both quinine and 9-aminoacridine it combined a known antimalarial with a known antimicrobial. The result was a useful, relatively nontoxic antimalarial, although it stained the skin and eyeballs yellow. Despite this side effect and a high incidence of gastrointestinal disturbance, quinacrine was widely used during World War II by European troops in East Asia. The availability of the results of medicinal chemistry research to both sides in wartime is a curious feature of antimalarial development, highlighted below.



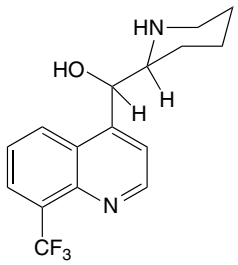
(**162**) Quinacrine (mepacrine)

As has been explained, the major stimulus for research into synthetic antimalarials was not so much the therapeutic inadequacy of quinine as the potential lack of availability in times of social upheaval. During World War II, the United States encouraged the planting of cinchona in Costa Rica, Peru, and Ecuador. The total synthesis of quinine was too difficult in the 1940s and is unlikely to become economically viable even in the new millennium. This problem was partly overcome with quinacrine, which was used widely in World War II, although quinacrine has the defects described earlier. The conceptual derivation of chloroquine (**163**) from quinacrine is obvious and apparently happened twice, in Germany and the United States, the latter about 10 years after the Germans had discarded the drug as being too toxic! The story of the rediscovery of chloroquine is fascinating, as an account of human muddle and misjudgment, finally leading to an extraordinarily valuable drug.



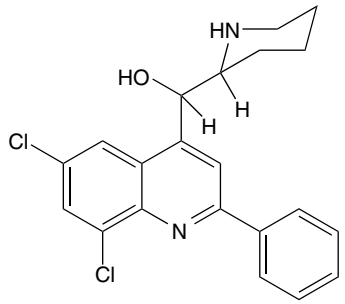
(**163**) Chloroquine

Over decades of sublethal exposure, the resistance of all types of malaria has increased to a point where chloroquine no longer offers certain protection. With the partial exception of quinine and dihydroquinine, resistance to antimalarials had reached the stage at the time of the Vietnam War where more research was required. The development of mefloquine (**164**) was a continuation of the World War II effort, with a gap of about 20 years. Resistance to chloroquine had developed widely during that period, but surprisingly less so to quinine, given the obvious similarities in structure. This observation stimulated a reappraisal of quinolines, known as *quinoline methanols*, which bear a hydroxy

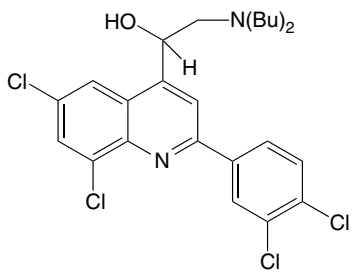


(**164**) Mefloquine

group on the α-carbon of a substituent attached to the 4-position. Up to 1944, a total of 177 quinoline methanols had been synthesized and tested, resulting in one compound (**165**) with activity superior to that of quinine. In human volunteers there was a high incidence of phototoxicity associated with (**165**), so research on quinoline methanols in 1944 had ceased in favor of the 4-amino series, which included chloroquine. Reappraisal of about 100 of the World War II compounds confirmed the high activity and phototoxicity of (**165**) and also showed the high potency of an analog (**166**), which had reduced phototoxicity. These data, together with results from about 200 newer compounds, fostered the belief that phototoxicity was separable from antimalarial activity. Extensive evaluation of (**166**) in humans with chloroquine-resistant *P. falciparum* infections showed promise, but with a significant incidence of toxic reactions; the dose required was also inconveniently large.



(**165**)



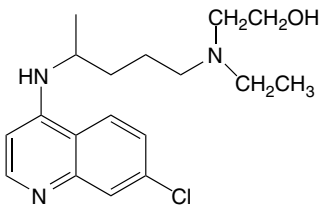
(**166**)

Two hypotheses concerning the effect of the 2-phenyl substituent were proposed. One was that metabolic oxidation was blocked at this position, so that duration of action was prolonged, which was considered desirable. Second, the UV chromophore was enlarged, which would increase the likelihood of drug-induced photosensitivity. The phenyl substituent was thus replaced by trifluoromethyl in the 2-position. Before the first such derivatives were tested, further analogs were prepared with an additional trifluoromethyl group on the benzene ring. This was serendipitous because the first series of 2-trifluoromethyl analogs had low potency and were also photosensitizing. The series with two trifluoromethyl groups, one at position 2 and another in the 6-, 7-, or 8-position were all potent and free from phototoxicity. The most potent was mefloquine (**164**), a very successful drug, but one that produces unacceptable CNS effects in a small proportion of users; parasite resistance has also been observed in parts of Southeast Asia. There is now a serious attempt by the World Health Organization and groups such as the Medicines for Malaria Venture Foundation to find new antimalarials.

Physicians are pragmatic when choosing therapy for patients whose suffering is not alleviated by accepted methods. A drug that has been shown to be toxicologically safe may be utilized in a new area for the flimsiest of reasons. Thus, Page described his use of quinacrine in two cases of lupus erythematosus as being based on "[a] chance observation. . .," although he did not describe the observation that led to his decision. He did, however, record

that quinine had been tried previously and "prevented extension of the lesions," so this may have been the basis for his rationale. In any event, the beneficial effects of quinacrine were remarkable and appeared to be related to the degree of yellowing of the skin that, as described earlier, is a common side effect of the use of quinacrine in malaria.

Among Page's group of patients with lupus erythematosus were two with rheumatoid arthritis, whose symptoms also responded to treatment with quinacrine. The following year, other physicians conducted a trial of quinacrine on a larger group of patients with rheumatoid arthritis; the results encouraged Haydu to test chloroquine on similar patients, again with positive results. A year later, two more physicians compared quinacrine with chloroquine and found the latter to be better tolerated, the majority of patients gaining some benefit. Both quinacrine and chloroquine caused gastrointestinal disturbances, which led to a trial of hydroxychloroquine (**167**), an unsuccessful antimalarial but with less effect on the gut, thus allowing larger doses to be given. Hydroxychloroquine has remained part of the standard drug therapy for rheumatoid arthritis ever since.



(**167**) Hydroxychloroquine

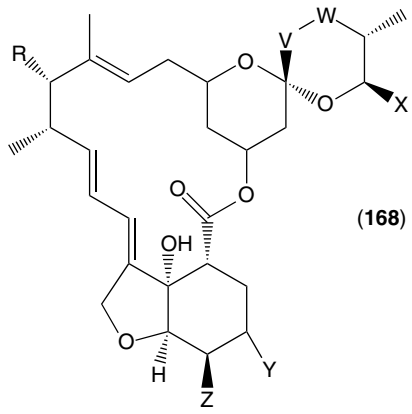
So far, the choice of quinine-like drugs to treat rheumatoid arthritis has been based on preliminary selection as antimalarials. Because the two types of action are presumably unconnected, there might be some value in a screening program aimed directly at rheumatoid disease.

8.3 Avermectins and Milbemycins

There is no major distinction between the avermectins and milbemycins, which are based on the same complex polyketide macrocycle (**168**): the avermectins are oxygenated at C-13 and bear a disaccharide on this oxygen. They have been isolated from cultures of a number of *Streptomyces* species, obtained from all over the world.

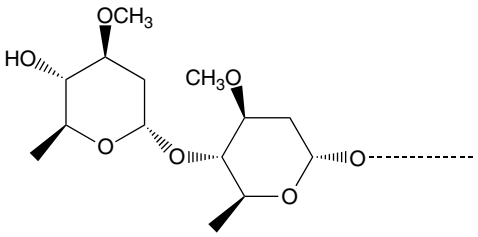
The avermectins, particularly, have been the subject of intense commercial interest because they possess potent activity against both nematode and arthropod parasites of livestock. A full discussion of structure–activity relationships would be out of place here, not least because the data are voluminous, so we shall concentrate on the development of ivermectin, which has been a major success.

Structural designation of avermectins is quaintly based on three series: A, B; a, b; and 1, 2. Greater activity resides in the B series, with a free OH at position 5. There is little difference in potency between the a and b series. In the more potent B series, there are important differences between the 1 series and the 2 series; B_1 is the more active orally, whereas B_2 is the more potent by injection. There are also differences in their spectrum of activity. The spectrum of activity was kept as broad as possible by hydrogenation of a mixture of avermectins B_1a and B_1b to give ivermectin (**169**), which contains at least 80% of 22,23-dihydroavermectin



(**168**)

Avermectins R =



Milbemycins R = H

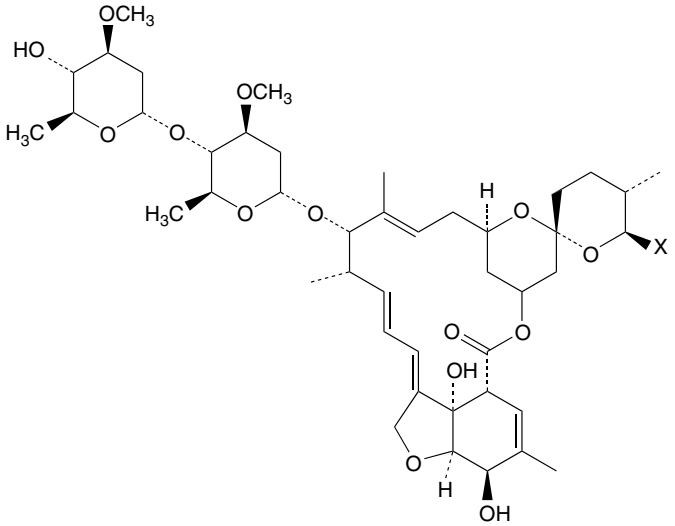
In the avermectins the series are designated as follows (Y = CH_3):

A, Z = CH_3
B, Z = H
a, X = $CH(CH_3)CH_2CH_3$
b, X = $CH(CH_3)_2$
1, V-W = CH═CH
2, V-W = $CH_2CH(OH)$

In (**169**), V-W = CH_2CH_2, X = $CH(CH_3)CH_2CH_3$ (major) or $CH(CH_3)_2$ (minor), Y = CH_3 and Z = H

B_1a and not more than 20% of 22,23-dihydroavermectin B_1b.

Ivermectin was developed for, and has been highly successful in, the treatment and control of parasites in cattle, horses, sheep, pigs, and dogs. Following studies in humans with river blindness (onchocerciasis), the developers of ivermectin have participated in a major program aimed at eradication of the disease. The sufferers inhabit some of the poorest parts of Africa and cannot pay for their treatment, so the drug has been donated by Merck and Co. Since 1996, more than 20 million treatments have been given. The drug does not kill the adult worms that cause onchocerciasis, but is useful in interrupting the life cycle. Ivermectin is also of value in treatment of scabies. A great deal of information on the biological



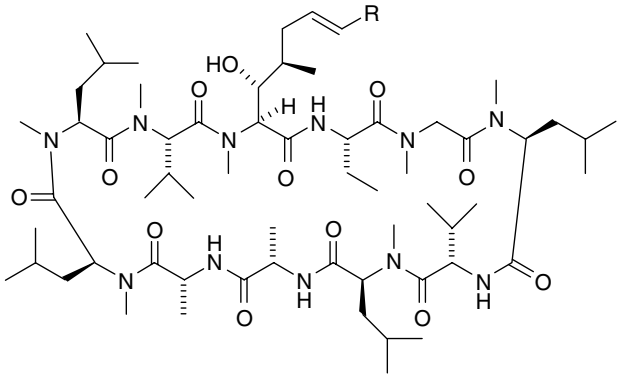
(**169**) X = $CH(CH_3)CH_2CH_3$ (major) or $CH(CH_3)_2$ (minor)

aspects of the use of ivermectin has been published.

9
Immunosuppressant Drugs

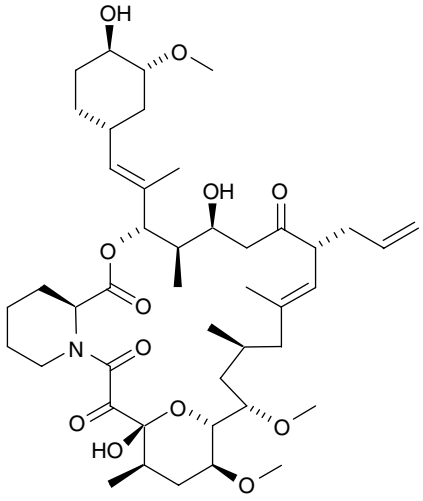
9.1
Cyclosporin, Tacrolimus, and Sirolimus

The discovery that the cyclic polypeptide, cyclosporin (**170**), acts as a T-cell selective immunosuppressant by inhibiting calcineurin has lead to a revolution in organ transplantation and related clinical practice. Cyclosporin is produced by fermentation of the fungus *Tolyplocladium inflatum* and was first approved in 1978 for prevention of kidney allograft rejection. The drug is now also used to prevent liver, heart, lung, and bone marrow transplant rejection and for the treatment of psoriasis, atopic dermatitis,



(**170**) R = CH_3
(**171**) R = $CH{=}CH_2$

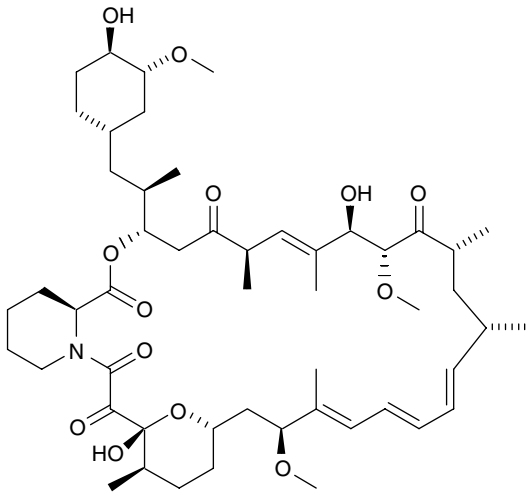
rheumatoid arthritis, and nephrotic syndrome. A semisynthetic alkene analog of cyclosporin, ISA-247 (**171**), is undergoing clinical trials for prevention of kidney allograft rejection and for treating psoriasis. Two other fermentation products have also played a pivotal role in transplant surgery, that is, the macrolides, tacrolimus (FK506) (**172**) from Astellas and more recently, sirolimus (rapamycin) (**173**) from Wyeth. These drugs are produced by fermentation of *Streptomyces tsukubaenis* and *Streptomyces hygroscopicus* respectively. Various derivatives of sirolimus (**173**), which blocks activation of the lipid kinase mTOR (mammalian target of rapamycin), are being evaluated as anticancer agents.



(**172**)

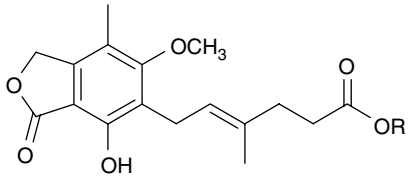
9.2 Mycophenolic Acid and Mycophenolate Mofetil

Finally, mycophenolic acid (**174**), first isolated in 1896 from various cultures of Penicillium was found to inhibit inosine monophosphate dehydrogenase and, as a result, selectively block DNA synthesis in lymphocytes. A prodrug of mycophenolic acid, mycophenolate mofetil (**175**), shows improved bioavailability and is now approved in many countries for use in



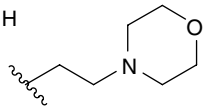
(**173**)

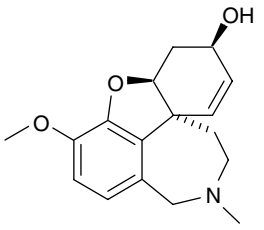
combination with cyclosporin to prevent kidney allograft rejection.



(**174**) R = H

(**175**) R =





(**176**)

10 Conclusion

Natural product research has been the single most successful strategy for discovering new pharmaceuticals and has contributed dramatically to extending human life and improving clinical practice. As long as Nature continues to yield novel, diverse chemical entities possessing selective biological activities, natural products will play an important role as leads for new pharmaceuticals. An interesting example is the alkaloid galantamine (Nivalin, Reminyl) (**176**), originally isolated from the bulbs of the Amaryllidaceae family (snowdrops, daffodils, etc.), which has found use in the symptomatic treatment of Alzheimer's disease. It is a reversible and competitive inhibitor of acetylcholinesterase that also interacts allosterically with nicotinic acetylcholine receptors to potentiate the action of agonists. By acting to enhance the reduced central cholinergic function associated with this disease, significant improvements in cognition and behavioral symptoms have been observed in patients. In this case, it is the alkaloid itself that is used as the active compound and it will be interesting to see whether development leads to better drugs. There are as yet relatively few publications in this area.

Over 90% of bacterial, fungal, and plant species are still waiting to be investigated. High-throughput screening methods will allow large numbers of samples to be tested against more biological targets. An alternative view is that the elucidation of the biological effects of chosen compounds, in some detail, will yield insight into biological processes that may open avenues for medicinal chemistry research that is not based on pure chance. This view is based on the recognition that secondary metabolites have been produced and ruthlessly selected, by evolution, over a long period of time. Either way, the medicinal chemist has a wonderful opportunity to continue utilizing the rich chemical diversity offered by Nature.

The best approach for the identification of natural product leads is a matter of debate. Some very inventive techniques have been used for sample mixtures (extracts) by the bioassay-guided method; for example, by combining automated sample injection/fraction collection with the use of modern stationary phases for column chromatography and appropriate biological assays, active compounds can be readily isolated from crude extracts in just a few

days. An alternative is to use an ethnobotanical or ethnopharmacological technique, whereby the accumulated wisdom of many generations of native plant users may be harnessed in the search for better medicines for all. These two techniques may be combined, so that the native people describe the uses to which they put the plant and the researchers devise a bioassay that is used to find the active components. The problem with any bioassay-guided technique, however, is that the inactive constituents are not identified. This represents a potential waste, given that the microbial strain or plant specimen has had to be collected, preserved, and identified. An alternative approach is to use high-performance liquid chromatography coupled with modern detection technologies (UV, evaporative light scattering, mass spectrometry) to first reduce a microbial culture or plant extract to its secondary metabolites, either as semipurified mixtures or single compounds: the products are then able to be screened for biological activity in a high-throughput manner and the samples can be reevaluated when new screens become available. One thing is certain: the variety of natural product structures, after perhaps 300 million years of natural selection, far exceeds the bounds of human imagination and continues to offer exciting possibilities for novel drug discovery.

Keywords

Biomaterial
Any material from either natural or synthetic sources used for biological applications, to replace or substitute for biological function of living cells or tissues.

Extracellular Matrix (ECM)
It is a meshwork of large fibrillar and globular glycoproteins and hydrophilic proteoglycans, secreted by cells. ECM plays an important role in cell and tissue structure and organ morphogenesis and function by providing biochemical and mechanical signaling to cells and, in combination with interstitial fluids, provides resistance to tensile and compressive stresses.

Hydrogel
It is a soft viscoelastic meshwork that consists of two or more components, one of which is water.

Mechanical Stress
Includes pressure (force acting perpendicular to a surface), shear (force acting parallel to a surface), or stretch, all of which influence the development, remodeling, and pathology of tissues.

Tissue Bioengineering
Formation of tissue *de novo* by promoting cell proliferation and differentiation *in vivo* or *ex vivo* using a physiologically relevant microenvironment and primary cells or appropriate cell lines.

The basic principle of three-dimensional (3D) cell cultures is to place cells in conditions that induce formation of multicellular, tissue-like structures developing in X, Y, and Z planes. The 3D structures are characterized by establishment of adhesion complexes and tissue polarity, and by changes in cytoskeletal structure and cell volume that are significantly different from those found in cells cultured as monolayers (2D). As a result, the phenotypes, function, and regulation of signaling pathways under 2D and 3D conditions are fundamentally different. The science, as well as the art, of 3D cultures center around the recapitulation of physiological behaviors found in the organism, where reciprocal and dynamic cell–cell and cell–ECM interactions affect intracellular biochemical and structural signals, and hence influence gene expression and homeostasis. The 3D culture systems provide unique opportunities to mimic many aspects of developmental and pathological phenomena, to elucidate molecular mechanisms, and to produce tissues for transplantation purposes. With apologies to many colleagues whose works are not cited, this chapter relies heavily on the examples from the authors' laboratories using mammary epithelial cells. This is partly because we are most familiar with this tissue and also, many of the details for mammary models have been worked out in nearly three decades. As such, the experience with mammary acinus is used as a possible road map for other tissues.

1
Three-dimensional (3-D) Cell Culture: Cell Shape, Tissue Structure, and Biochemical Signaling

1.1
The Discovery of Extracellular Matrix (ECM) Signaling

The existence of extracellular matrix (ECM) has been recognized since the origin of microscopy. The term extracellular matrix was proposed following the discovery of cells within connective tissues during the nineteenth century. It was defined as the material outside the cells. The importance of this structure for cell behavior was first suspected when quantitative changes in the density of the ECM were seen to affect cell adhesion properties. This phenomenon was well described

for the adhesion between lens rudiment and the optic vesicle, a process critical for lens cell spreading and during chronic inflammatory changes in the lungs.

During the 1970s, major observations established the importance of the ECM in developmental processes, and cell biologists showed that the different cell types were capable of responding to physical and biochemical influences of the ECM and also secreting ECM components.

These discoveries suggested the existence of a reciprocal relationship between the cells and their ECM (detailed in the following sections) and led to the postulate of the model of dynamic reciprocity between the ECM and the cell nucleus. The model integrated both the physical and biochemical connections between the putative ''ECM receptors,'' the cytoskeleton, the nucleus, and chromatin. Thus, the combined work of cell and developmental biologists as well as biochemist in this area, set the stage for an astonishing scientific adventure aiming at deciphering the role of ECM in development, tissue specificity, and gene expression.

1.1.1 Plasticity of the ECM

The ECM represents a complex world of intricate molecular interactions and is characterized by an enormous diversity in morphology and composition. It is composed of fibrillar molecules such as collagens and elastin and glycoproteins such as fibronectin, laminins, and hydrophilic proteoglycans. In addition, soluble molecules such as growth factors or cytokines can be attached to, trapped, and released from the ECM. The ECM acts as a hydrogel in which fibrillar proteins interact within the hydrated network of the glycosaminoglycan chains of proteoglycans. The combination of the hydrogel properties with the diversity of ECM composition is critical for the function of each type of tissue.

The existence of a different ECM composition depending on the tissue type and/or the degree of tissue maturation was reported almost half a century ago. One of the striking examples of ECM plasticity occurs during skeletogenesis. At early stages, a hyaluronan-rich ECM is critical for mesenchymal cell migration and proliferation. Then, cartilage differentiation involves the removal of hyaluronan and the production of type II collagen and a specific chondroitin sulfate proteoglycan. Additionally, a more specialized ECM organization is seen in the epiphyseal growth plate, and also at the site of initiation of bone formation, which is characterized by a switch of collagen synthesis from type II to type I, and depletion of proteoglycans.

The diversity of ECM composition was soon linked to the fact that different cell types (e.g. mesenchymal, endothelial, and epithelial cells) within a tissue are capable of producing a wide range of ECM molecules. Smooth muscle cells were shown to synthesize connective tissue matrix components, including collagen, elastin, and glycosaminoglycans in the arterial system and other smooth muscle-rich tissues (e.g. uterine myometrium), indicating that the same cell type has the capacity to elaborate soluble, as well as insoluble, components of the ECM. Similarly, endothelial and epithelial cells were shown to synthesize the collagens and glycoproteins of basement membranes (BM, a specialized form of ECM) found around vessels and at the interface between epithelial and connective tissues. The demonstration that the different cell types were capable of synthesizing ECM proteins relied on the ability to culture cells

ex vivo. The ECM components released into the culture medium were found to be similar to that of molecules observed in human tissue, hence confirming that cells were at the origin of ECM production. For instance, fibronectin secreted by human endothelial cells in culture was identical to the fibronectin found in human plasma, and fetal epithelioid cells in culture synthesized type IV procollagen similar to that of collagenous proteins extracted from the tissue's BM.

1.1.2 ECM Signaling Encompasses Specific Cell Membrane Receptors

The observation of a meshwork of ECM molecules on the cell surface suggested a close interaction between cells and ECM molecules. An early milestone in the study of cell–ECM interactions came from work largely pioneered by Hay and colleagues. In an elegant series of experiments, they demonstrated that contacts between cells and the ECM were necessary to sustain the stimulatory effect of ECM on corneal epithelial collagen synthesis. Notably using filters of different pore sizes and thickness, they showed a linear correlation between the cell surface area in contact with the ECM and production of collagen. Many more reports followed describing both the positive and negative regulation of ECM components by cell–ECM interactions. For example, chondrocytes synthesize chondroitin sulfate in the presence of extracellular chondroitin sulfate, whereas they stop synthesis in the presence of hyaluronan.

Early indications that the ECM was influencing cell behavior came from observations that the morphology and biochemistry of normal parenchymal liver cells and normal mammary epithelial cells from prelactating mice were modified upon culture in the presence of collagen I gels compared to tissue culture plastic. Similarly the ECM was shown to influence metabolic pathways and cell proliferation. It was shown later that the ECM in general and the BM, in particular, also controlled cell survival.

Numerous specific ECM receptors have now been identified including prominent transmembrane proteins, the integrins. It is well established that the binding of ECM molecules to cell membrane receptors triggers intracellular signaling, which ultimately reaches the cell nucleus and influences gene expression. Although integrin signaling is quite complex, a major principle of this signaling clearly includes the existence of central signal transducers (e.g. FAK) that can bind to, and recruit other signaling molecules. This network of signaling molecules is connected to the cytoskeleton. Additionally, it has been shown that integrins and growth factor receptors cooperate to control major cellular events such as proliferation. This cooperation is critical to transmit signals via specific signaling cascades. Further transmission of ECM signaling to the cell nucleus partly relies on the nuclear translocation of signaling molecules that are first activated in the cytoplasm. As described in other sections of this chapter, ECM receptors participate also in mechanotransduction where forces affect cytoskeletal organization and signaling cascades, and ultimately influence the cell phenotype. Notably, the interaction between the cytoskeleton and signaling molecules is thought to be critical for changes in cell phenotype resulting from mechanical influence. Thus, both structural (e.g. via cytoskeletal rearrangement) and biochemical aspects of ECM signaling should be integrated to develop a complete view of the control of cell behavior.

1.1.3 ECM-response Elements

A direct connection between ECM signaling and gene regulation was described several years ago upon the discovery of ECM-response elements in several gene promoter sequences. The first ECM-response element was identified and characterized in the enhancer region of the β-casein gene, which is turned on in mammary epithelial cells upon contact between the cells and laminin. It was shown later that chromatin remodeling is involved in regulation of the ECM-response element of the β-casein gene. We identified also a negative ECM-response element and a few other positive elements in the promoters of the TGF-β1 (transforming growth factor) gene and tumor viruses, although these were not characterized in detail. An ECM-response element was identified also in the promoter of LpS1 genes in sea urchin, indicating that ECM-specific signaling to the genome may be a conserved phenomenon. In the latter study, it is proposed that ECM *disruption* triggers a signal that induces a remodeling of binding factors in the ECM-response element and turns off LpS1 gene activity. Thus, both cell adhesion and release of binding to ECM are capable of triggering local chromatin remodeling.

1.2 Geometry Matters

It was originally thought that the ECM had a purely physical role by providing a scaffold to maintain the shape of the organs. However, upon identification of ECM receptors and evidence of ECM signaling, intracellular biochemical pathways triggered by cell adhesion to ECM molecules became an important research focus. In addition, the role of cell shape in ECM-induced mechanical and biochemical signaling is beginning to be accepted, and is an active area of investigation.

1.2.1 The ECM Controls Cell Shape

The influence of the ECM on cell shape was already reported in the early days of ECM research. For instance, it was clear that axon extension and orientation was dependent on the contact with extracellular fibrils. Early on, Bornstein and colleagues suggested that the extracellular meshwork of ECM molecules was interacting directly or indirectly with the internal cytoskeleton, hence mediating changes in cell shape. Today, we can appreciate the importance of this hypothesis since ECM-mediated cell shape appears to play a critical role in the control of gene expression and cell phenotype, and the cytoskeleton appears to be essential for transmission of signals.

Using surfaces with dots of ECM regularly distributed and separated by non-adhesive regions, Singhvi and colleagues demonstrated that the number and distribution of available ECM binding sites dictate cell shape, spreading, and migration. More recently, it was shown that contacts with spacing between 5 and 25 μm trigger cells to adapt their shape, while the extent of cell spreading is correlated with the total surface covered by the ECM. Integrins were identified as critical receptors for the mechanical effect of the ECM. These transmembrane ECM receptors appear to act as anchor molecules that react to the tension exerted by binding to the ECM molecules. By resisting mechanical loads that are applied to ECM receptors, ECM molecules contribute not only to changes in cell shape but most probably also to the arrangement of cells into specific multicellular structures during tissue morphogenesis.

1.2.2 Cell Adhesion to the ECM Triggers Intracellular Reorganization

Whereas it was relatively straightforward to show the relation between the ECM molecules and the cytoskeleton, how ECM may influence structures beyond the cytoskeleton, such as the cell nucleus, has remained unclear. It has been shown that the mechanical effect induced by ECM on integrins is also accompanied by the deformation of the shape of the cell nucleus as well as the redistribution of nucleoli along the axis of the applied tension field, but much less is known about the subsequent alterations within the molecular organization of the nucleus. Nevertheless, there are reports suggesting an effect of cell shape change on gene expression. The simple fact is that certain cell types can adopt a rounded shape when cultured in the presence of certain ECM components instead of the flat shape seen in 2D cultures, and this is sufficient to induce or suppress the expression of certain genes. Such is the case for the expression of the milk protein, lactoferrin, which is turned on upon laminin-rich ECM-induced roundup of mammary epithelial cells. This effect of ECM is essentially mechanical since it can be reproduced without ECM when cells simply are cultured on the nonadhesive substratum, polyhema, which has been used for decades to show the effect of cell shape on growth regulation.

We have shown that ECM signaling is accompanied with the reorganization of certain nuclear structural proteins such as NuMA, and the cell proliferation regulator, retinoblastoma protein as well as changes in the expression and/or distribution of chromatin components. However, the role played by biochemical signaling versus mechanical signaling in nuclear organization is not clear yet. It will be difficult to sort out a direct ECM effect on nuclear components from an indirect effect due to alterations in gene expression. Indeed, changes in nuclear organization may be a consequence of alterations in gene expression that are associated with changes in chromatin structure and possibly modification of the RNP (ribonucleoprotein) network that has been proposed to connect structural nuclear proteins.

1.3 Why 3D?

The art and science of cell culture started more than a half century ago when Alexis Carrel grew a small piece of chick embryo on a fibrin clot, *ex vivo*. Since then, almost all cells have been cultured on tissue culture plastic. It is in fact remarkable that so many cells can survive when cultured in such extreme conditions, on a plastic surface without their regular microenvironment and in the presence of exogenous factors, which are often fluids that the cells do not encounter directly *in vivo*, as is the case of media containing serum (serum is clotted blood and contains excess growth factors and cytokines released from lysed platelets and other blood cells). Cells cultured on tissue culture plastic are referred to as *monolayer or two-dimensional (2D) cultures*. This is the standard method of culturing cells and has permitted numerous discoveries, including the identification of the different components of the cell machinery and regulatory principles of fundamental cellular events such as proliferation, adhesion, and cell death. However, almost all cells change function drastically in such cultures compared to *in vivo* situation, and differentiated normal cells essentially lose their ability to express tissue-specific genes. While the recognition for the need to ''grow'' cells

in more physiological settings started in the 1970s, it is only recently that this concept has gained a more universal appeal (Fig. 1). This is especially so because it is now appreciated that important signaling pathways are regulated differently in 3D compared to 2D. Moreover, the study of nuclear organization has revealed significant differences between cells cultured under 2D and 3D conditions; the latter recapitulates the organization observed in tissue sections.

"Do not ask what a cell can do, ask what it does do!" (Gloria Hepner, personal communication). What happens in 2-D cell culture is what a cell *can* do, so the

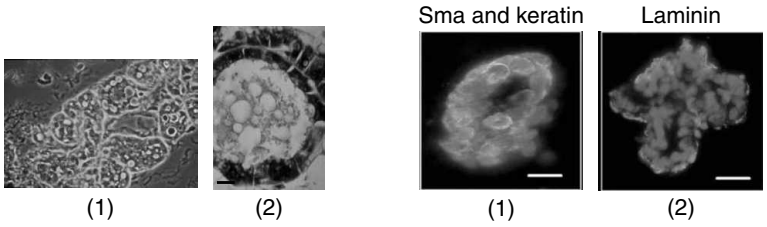

Fig. 1 (a) (1) Thick section through a midpregnant mammary gland shows the gross structure of developing alveolar buds. A dual exposure in which cells are viewed by Nomarski optics and the laminin visualized by rhodamine fluorescence. Bar 10 μm. (From Streuli and Bissell, 1991.) (1977) Maintenance and induction of morphological differentiation in dissociated mammary epithelium on floating collagen membranes, *In Vitro* **13**, 316–328, with permission of the publisher; schemes are adapted from Streuli and Bissell, 1991.) (See color plate p. xl.)

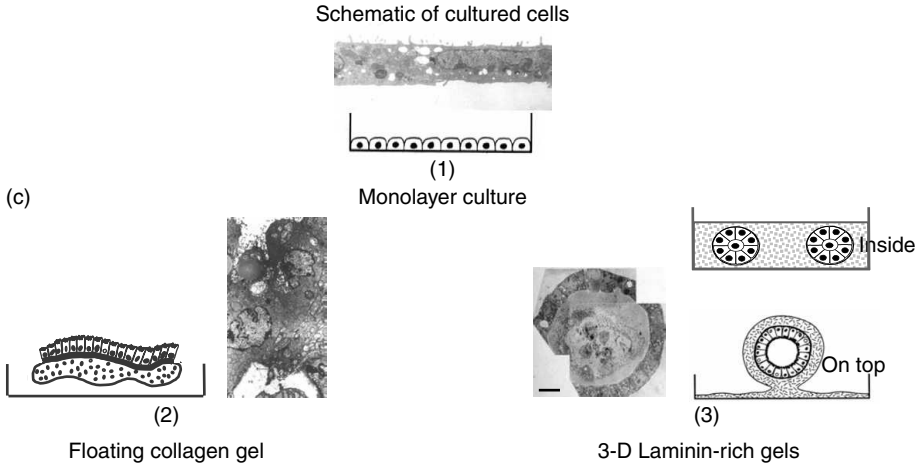

Fig. 1 (*Continued*)

challenge is to find out how one studies what the cell *does* do. Organ cultures are one approach, but unfortunately, this type of culture is usually short lived; the center of the explants becomes necrotic while fibrosis develops in the remaining live tissue. In contrast, 3D cultures within a malleable ECM permit the recapitulation of aspects of cell behavior that are physiologically relevant in a simplified environment as shown with mammary, liver, skin, pancreas, lung, prostate, salivary, thyroid, kidney, endothelial, intestinal, and bone cells.

Not surprisingly, as ECM molecules were being shown to signal to cells, alterations in cell–ECM interactions began to be viewed also as key events in the development of pathologies. Changes in the relationship between cells and the ECM include degradation of ECM molecules via the action of proteases. A striking example is that of the invasive phenotype of cancer cells. Alterations in the secretion of ECM components associated with pathologies were also described early on. Specifically, biochemical defects due to alterations in collagen synthesis were reported in humans as early as 1972. More recently, diseases that are emerging as the twenty-first century's new medical challenges have also been associated with alterations in the interaction between cells and their ECM. Indeed, the major pathological trait of muscular dystrophies is the inability to form correctly glycosylated dystroglycans, hence resulting in the lack of proper adhesion to laminin. Potential treatment strategies aim at promoting the reestablishment of cell–ECM interactions necessary to sustain muscle activity by targeting certain glycosyl transferases that stimulate dystroglycan glycosylation. Defect in dystroglycan has been proposed to play a role also in breast cancer.

3D cultures help greatly in unraveling mechanisms involved in normal and pathological developments because their experimental setup is based on established knowledge. We know that contact with appropriate ECM is critical for cell behavior and shape, and that specific soluble factors are required for the optimal function of tissues. Placing cells in the correct microenvironment promotes the formation of tissuelike 3D structures that develop in the X, Y, and Z planes. Thus, 3D cultures

provide a controlled microenvironment, the complexity of which may be increased to recapitulate additional features of the natural cellular environment. However, it is important to remember that ultimately the art and science of 3D cultures rely on the ability to test the system chosen for compliance with tissue or organ physiology *in vivo*. Thus, it is also crucial to know the limits of a particular system that is being used.

2 Setting up the Culture System

When thinking about setting up 3D cultures, it is important to take into account the physiological and histological studies performed on the tissue of interest. The culture system should allow the necessary readout for a particular question being asked without compromising the phenotype being studied. Once the necessary environment has been established, quality control has to be maintained throughout the experiment, whether the goal is to investigate a particular signal transduction pathway or to propagate cells for tissue replacement.

As described in the preceding sections, cell behavior is influenced by shape and chemistry. The 3D culture system has to address both of these aspects, but an ECM-like scaffold is usually not sufficient to provide the complete endocrine and paracrine milieu. Therefore, specific soluble factors, including growth factors and hormones should also be provided.

To illustrate the different aspects of 3D cultures, examples described in the following sections will be taken mainly from the monoculture of rodent and human mammary cells, a system we helped develop and thus are particularly familiar with. Nevertheless, the logic associated with setting up the correct 3D culture systems can be applied to any cell type. Cell coculture systems that combine several cell types will be discussed in Sect. 4.3 of this chapter. Monoculture, or monotypic cell models, refers to cell culture models involving one cell type, whereas coculture, or heterotypic cell models, refers to cell culture models involving two or more cells types.

2.1 Choice of the Extracellular "Gel" and Other Substrata

2.1.1 The ECM

Although most cell types studied so far have been shown to synthesize ECM components, setting up 3D cultures usually requires the use of either natural or synthetic exogenous ECM, in order to provide the scaffold necessary for initial cell shape change and to trigger the biochemical signaling necessary for differentiation-linked growth arrest and morphogenesis in nonneoplastic cells. Almost all cells make their own ECM environment and depending on factors such as cell type and tissue polarity, the ECM can be deposited as an organized structure that envelopes the multicellular structures (e.g. the BM in polarized epithelia) and is formed against the exogenous substrata.

The choice of the exogenous ECM depends on the tissue type; however, ECM components should be provided as a *hydrogel,* and not as a solid substratum, in order to comply with major physical characteristics of natural ECM environments. Normal epithelial and endothelial cells abut BM components, while normal mesenchymal cells are in contact with connective tissue ECM. In contrast, even when they originate from epithelial tissues, invasive

tumor cells both make, and are in contact with, connective ECM and often make aberrant amounts of BM components. The need for specific ECM components for structural and functional differentiation of mammary cells was demonstrated early on. We showed that mouse mammary epithelial cells made milk proteins if they were cultured on Matrigel™ or laminin-1, but would not do so in response to collagen I or fibronectin. Later, in collaboration with the Petersen laboratory we showed that the assay could be used also for distinguishing normal and malignant human breast epithelial cells, and that nonneoplastic mammary epithelial cells would not form polarized structures (acini) in 3D collagen I gels unless laminin-1 (but not laminins-5 or 10/11) was present. The characteristics that are used as a readout for proper acinar differentiation of breast luminal cells (Table 1) signify two important features of 3D cultures: First, given the appropriate milieu, the epithelial cells create their own endogenously produced ECM by secreting and organizing ECM components into a BM (e.g. human epithelial cells make the BM component, collagen IV, when cultured in the presence of exogenous laminin-rich Matrigel™ from murine origin). Second, vectorial secretion into the lumen indicates that this 3D culture setting recapitulates the formation of a polarized tissue structure signified by the presence of a polarity axis defined by an organized BM, lateral cell–cell junctions and apical polarity markers (Fig. 2). The formation of a polarity axis is characteristic of all epithelia and is indispensable for proper tissue function. Surprisingly, a 3D culture system made of a malleable, laminin-1 containing gel appears to be sufficient to induce luminal cell lines to form the structural and functional characteristics of mammary acini (Fig. 2).

With the exception of collagen I, it is difficult to use pure ECM components because they do not gel easily and are cost prohibitive. There are other alternatives: Matrigel™, an ECM mixture that is rich in laminin-1 (about 80%) can trigger the formation of both mouse and human mammary acini. Although different preparations of Matrigel™ have slightly different compositions (see Sect. 2.2.1), it is, nevertheless, an acceptable choice as long as Matrigel™ lots are tested for recapitulation of the expected phenotype in the particular cell type being cultured.

Since the first description of the Matrigel™ use in mammary cells, our laboratory has developed a number of variations outlined in Fig. 3. An earlier study had indicated that addition of laminin to a collagen gel would allow rodent mammary cells to express milk proteins. More

Tab. 1 Evaluation of breast acinar differentiation using immunofluorescence for cellular and extracellular components.

General characteristics	*Markers of baso-apical polarity*
• One layer cells around the lumen as shown by DAPI-staining of cell nuclei	• Basal location of basement membrane components (e.g., laminin, collagen IV)
• Growth arrest as shown by absence of staining for BrdU and Ki-67	• Cell-cell junction location of beta-catenin and E-cadherin
• Cortical localization of F-actin in the cytoplasm	• Apical location of tight junction protein ZO-1
	• Apical location of Mucin-1

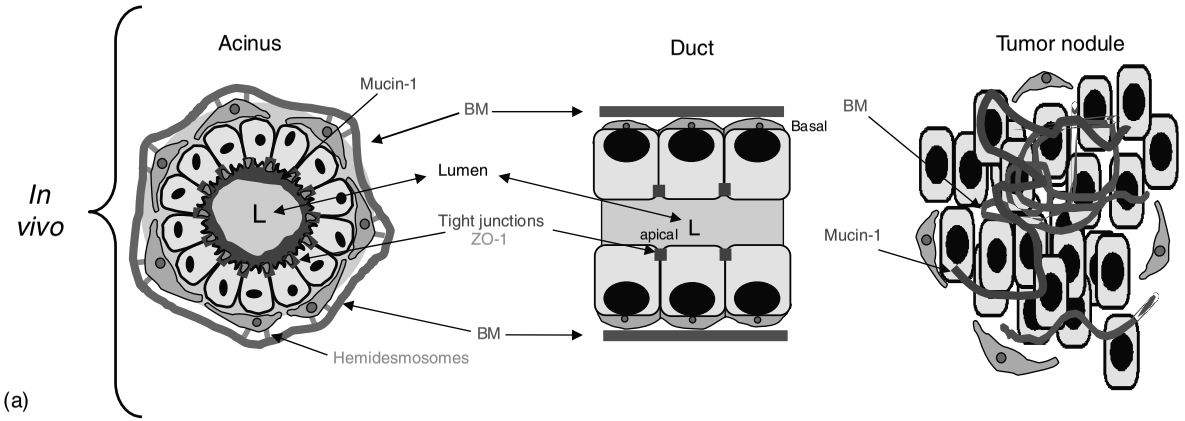

Fig. 2 Scheme of components of a polar acinus and alterations in tumors. (a) Schematic cross section through a mammary acinus (acinus) shows the typical polarized organization. From basal to apical poles: the BM (red), myoepithelial cells (myoeps) (green), luminal cells (eps) (yellow), apical mucin-1 (blue), and the lumen (L). Cell–BM junctions critical for basal polarity are represented in light blue (hemidesmosomes) and cell–cell junctions critical for apical polarity are represented in purple (tight junctions). The localization of a major organizer of tight junctions, ZO-1, is shown in pink. Similarly the polarity axis is shown on a longitudinal section of a normal tubular structure (duct). In contrast in tumors (tumor nodule), when BM components and mucin-1 are expressed and secreted, they are found throughout the multicellular structure and there is no distinguishable baso-apical polarity axis. Cell nuclei are shown in black. (b) In 3D monocellular culture, nonneoplastic epithelial mammary cells are plated as single cells in Matrigel and recapitulate the formation of acini-like structures with a polarity axis within a few days, whereas mammary tumors cells plated as single cells form tumorlike nodules in which mucin-1 and basement membrane components, when secreted, are observed throughout the multicellular structure and ZO-1 is either absent or observed in multiple locations including the cell nucleus and the cytoplasm (not drawn). Cell nuclei are shown in black. (Scheme for (b) is schematic drawing of results described in Petersen, O.W., Ronnov-Jessen, L., Howlett, A.R., Bissell, M.J., 1992.) (See color plate p. xliii.)

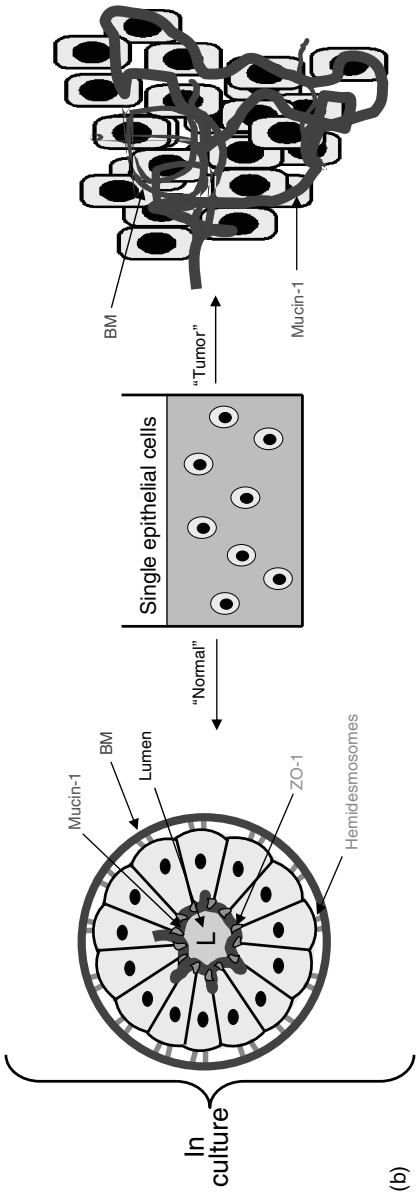

(b)

Fig. 2 (*Continued*)

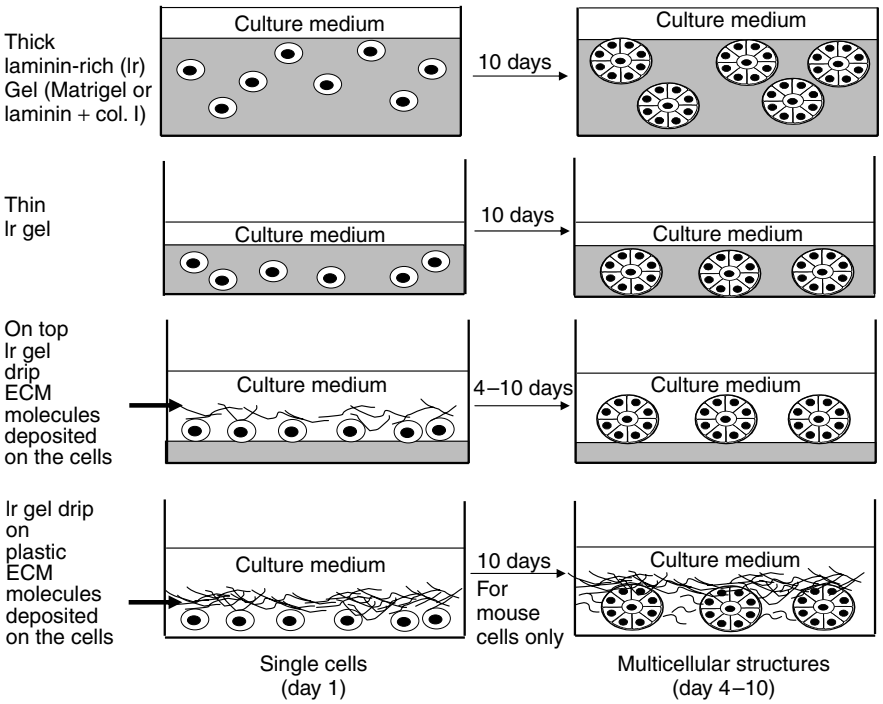

Fig. 3 Scheme of different types of 3D monocultures in the presence of Matrigel. Cells can be cultured as single cells in three different ways, including thick gel, thin gel, culture on top of thin Matrigel plus Matrigel drip, and culture on plastic surface with Matrigel drip (or Matrigel overlay). For primary epithelial breast cells and HMT3522-S1, the formation of multicellular structures that mimic acinar differentiation is observed by day 7, and is complete by day 10. Some mammary cell lines such as MCF10A take longer. We have recently developed techniques that allow formation of acini on top after 4 days (not shown). Although the three techniques using Matrigel generally lead to acini formation with human mammary epithelial cells, the Matrigel drip on tissue culture plastic gives rise to acini with certain cell lines only (e.g. murine cell lines). Matrigel is represented in light gray. Cell nuclei are shown in black.

recently, it was shown that in 3D collagen I gels, addition of laminin restores polarity to MDCK cells, and that addition of 10% laminin-1 to collagen I gels could mimic the formation of mammary acini. This method is particularly interesting because, in contrast to Matrigel™, it uses a controlled exogenous environment consisting of a well-defined scaffold, collagen I, and a relatively pure biochemical inducer, laminin-1.

Interestingly, when comparing the ability of laminin-1, Matrigel™, collagen IV, and fibronectin to induce the formation of acini using prostate epithelial cells, again only laminin-1 and Matrigel™ were efficient exogenous ECM environments confirming the importance of using appropriate BM components as initiators of differentiation. Laminin-1 was shown also to be critical for the formation of polarized acini by human submandibular epithelial cells as well as polarization of lung and kidney epithelial cells. Thus, a relatively similar gelatinous ECM scaffold may be used to initiate differentiation

of different types of epithelial cells with secretory functions.

2.1.2 The Other Components of the 3D Culture Milieu

Tissue differentiation would not be possible if the exogenous ECM and plain culture medium (i.e. medium lacking any additives) were the sole ingredients. Although serum has been of great help for culturing cells by providing necessary nutrients and proliferation and/or survival factors, its composition is poorly understood even now, and variations in its composition most certainly affect the phenotype of cells. It is imperative to culture cells in 3D using a defined culture medium specific for the cell type utilized. One of the earliest realizations of this was a demonstration using fetal human liver cells. Although different preparations of Matrigel™ have slightly different compositions (see Sect. 2.2.1), it is, nevertheless, an acceptable choice as long as lots are tested for the particular type of cells to be cultured, and for the recapitulation of the expected phenotype. As a rule of thumb, a defined medium contains generic survival factors as well as factors and hormones necessary for the differentiation of a particular cell type. For example, prolactin and insulin are important for acinar differentiation of mammary epithelial cells. Similarly, addition of testosterone is important for the differentiation of prostate cells. Growth factors are also chosen on the basis of the cell type. For instance, the epidermal growth factor (EGF) is critical for proliferation and differentiation of mammary epithelial cells. Thus, an understanding of cellular physiology will be particularly important to determine the exact composition of the medium.
